Package ‘philr’
March 23, 2017

Type Package
Title Phylogenetic partitioning based ILR transform for metagenomics data
Version 1.1.0
Date August 26, 2016
Author Justin Silverman
Maintainer Justin Silverman <jsilve24@gmail.com>
Description PhILR is short for Phylogenetic Isometric Log-Ratio Transform. This package provides functions for the analysis of compositional data (e.g., data representing proportions of different variables/parts). Specifically this package allows analysis of compositional data where the parts can be related through a phylogenetic tree (as is common in microbiota survey data) and makes available the Isometric Log Ratio transform built from the phylogenetic tree and utilizing a weighted reference measure.

clrp ................................................................. 5
**annotate_balance**

annotate a balance oriented with respect to the PhILR transform. That is, you can specify labels for the numerator (up) and denominator (down).

**Description**

**Usage**

```r
annotate_balance(tr, coord, p = NULL, labels = c("+", "-"), offset = 0,
                   offset.text = 0.03, bar = TRUE, barsize = 0.01, barfill = "darkgrey",
                   geom = "text", ...)
```

**Arguments**

- `tr`: phylo object
- `coord`: named internal node/balance to annotate
- `p`: ggtree plot (tree layer), if NULL then a new plot will be created.
- `labels`: label for the numerator and denominator of the balance respectively
- `offset`: offset for bar (if bar=TRUE) from tips
- `offset.text`: offset of text from bar (if bar=TRUE) or from tips (if bar=FALSE)
- `bar`: logical, should bar for each clade be plotted
- `barsize`: width of bar (if bar=TRUE)
- `barfill`: fill of bar
- `geom`: geom used to draw label (e.g., 'text' or 'label')
- `...`: additional parameters passed to geom_rect and specified geom

**Value**

ggplot object

**Author(s)**

Justin Silverman
buildilrBasep

References

Examples

```r
tr <- named_rtree(10)

annotate_balance(tr, 'n4', size=7)
annotate_balance(tr, 'n4', size=7, barsize=0.04, barfill='darkgreen', offset.text=0.05, color='red')
annotate_balance(tr, 'n4', bar=FALSE, size=7)
annotate_balance(tr, 'n4', bar=TRUE, size=7, labels=c('Num', 'Denom'), offset.text=.3)
annotate_balance(tr, 'n4', bar=TRUE, geom='label', size=8, offset.text=0.1)
```

---

buildilrBasep

Weighted ILR Contrast Matrix

Description

Weighted ILR Contrast Matrix

Usage

```r
buildilrBasep(W, p)
```

Arguments

- `W` sequential binary partition matrix (e.g., signary matrix; output of `phylo2sbp`)
- `p` weights (should not be closed)

Value

matrix

Author(s)

Justin Silverman (adapted from `gsi.buildilrBase`)

References

Examples

```r
p <- seq(.1,1,by=.2)
tr <- named_rtree(5)
sbp <- phylo2sbp(tr)
buildilrBasep(sbp, p)
```
calculate.blw  Calculate Branch Length Weightings for ILR Coordinates

Description

Calculates the weightings for ILR coordinates based on branch lengths of a phylogenetic tree via a few different methods (see details).

Usage

calculate.blw(tree, method = "sum.children")

Arguments

tree       a phylo class tree object that is binary (see multi2di)
method     options include: (default) 'sum.children' and 'mean.descendants' see details for more information.

Details

ILR balances built from a binary partition of a phylogenetic tree can be imbued with branch length information. This function is helpful in calculating those weightings.

There are a number of methods for calculating these weightings, the default 'sum.children' calculates the weighting for a given balance as the sum of its two direct children's branch length. An alternative that has been as yet less studied is 'mean.descendants' to calculate the weighting for a given balance as the sum of its two direct children’s branch lengths PLUS for each child the average distance from it to its descendant tips.

Note: That some trees contain tips with branch lengths of zero length. This can result in that tip being unreasonably downweighted, as such this function automatically adds a small pseudocount to those tips with zero length (equal to the smallest non-zero) branch length on the tree.

Value

vector of weightings for ILR coordinates produced via specified method.

Author(s)

Justin Silverman

See Also

philr

Examples

tr <- named_rtree(50)
calculate.blw(tr, method='sum.children')[1:10]
calculate.blw(tr, method='mean.descendants')[1:10]
**clr**p

---

### clr**p**

**Weighted CLR Transform**

---

**Description**

Weighted CLR Transform

**Usage**

```r
clrp(y, p)
```

**Arguments**

- `y`: shifted data matrix (e.g., output of `shiftp`)
- `p`: weights (should not be closed)

**Details**

Note that this function will close the dataset `y` to 1.

**Value**

matrix

**Author(s)**

Justin Silverman

**References**

**Examples**

```r
p <- seq(.1,1,by=.2)
c <- t(rmultinom(10,100,c(.1,.6,.2,.3,.2))) + 0.65  # add a small pseudocount
x <- miniclo(c)
y <- shiftp(x, p)
clrp(y, p)
```
convert_to_long  \hspace{1cm} Converts wide format ILR transformed data to long format

**Description**

Converts wide format ILR transformed data (see philr) to long format useful in various plotting functions where long format data is required.

**Usage**

```r
convert_to_long(df, labels)
```

**Arguments**

- `df` PhILR transformed data in wide format (samples by balances) (see philr)
- `labels` vector (of length `nrow(df)`) with labels to group samples by

**Value**

df in long format with columns

- sample
- labels
- coord
- value

**Examples**

```r
tr <- named_rtree(5)
df <- t(rmultinom(10,100,c(.1,.6,.2,.3,.2))) + 0.65  # add a small pseudocount
colnames(df) <- tr$tip.label
df.philr <- philr(df, tr, part.weights='enorm.x.gm.counts', ilr.weights='blw.sqrt', return.all=FALSE)
convert_to_long(df.philr, rep(c('a','b'), 5))
```

g.colMeans  \hspace{1cm} Geometric Means of Columns

**Description**

Calculates geometric mean of columns. Does not calculate WEIGHTED geometric means (vs. g.rowMeans)

**Usage**

```r
g.colMeans(x)
```
g.rowMeans

Arguments

x  matrix or vector

Value

vector (geometric mean of columns)

See Also

g.rowMeans

g.rowMeans

Examples

philr:::g.colMeans(rbind(c(2,4,4), c(2,4,4)))

g.rowMeans

Weighted Geometric Means of Rows

Description

Calculates weighted geometric mean (see references). Note if p=rep(1, nrow(y)) (default) then this is just the geometric mean of rows.

Usage

g.rowMeans(y, p = rep(1, nrow(y)))

Arguments

y  shifted data matrix (e.g., output of shiftp)

p  weights (should not be closed)

Value

vector (weighted geometric mean of rows)

References

See Also

g.colMeans

g.colMeans

Examples

p <- seq(.1,1,by=.2)
c <- t(rmultinom(10,100,c(.1,.6,.2,.3,.2))) + 0.65  # add a small pseudocount
x <- miniclo(c)
y <- shiftp(x, p)
philr:::g.rowMeans(y, p)
ilrp 

Weighted ILR Transform

Description

Calculated using weighted CLR transform (clrp)

Usage

ilrp(y, p, V)

Arguments

y
shifted data matrix (e.g., output of shiftp)
p
weights (should not be closed)
V
weighted contrast matrix (e.g., output of buildilrBasep)

Value

matrix

Author(s)

Justin Silverman

References

Examples

# Weights
p <- seq(.1,1,by=.2)

# Shifted Composition
x <- miniclo(c)
y <- shiftp(x, p)

# Contrast Matrix
tr <- named_rtree(5)
sbp <- phylo2sbp(tr)
V <- buildilrBasep(sbp, p)

ilrp(y, p, V)
mean_dist_to_tips  

**Mean distance from internal nodes to descendant tips**

**Description**

Calculates the mean distance from each internal node to its descendant tips

**Usage**

```r
mean_dist_to_tips(tree)
```

**Arguments**

- `tree`  
  a phylo class tree object that is binary (see `multi2di`)

**Details**

This is a function used by `calculate.blw` when `method='mean.descendants'`, there this function is called twice, once for each direct child of a given internal node and the results are summed for each node.

**Value**

vector (named if internal nodes are named)

**Examples**

```r
tr <- named_rtree(5)
mean_dist_to_tips(tr)
```

---

**miniclo**

**miniclo**

**Description**

small function to close (aka normalize by proportions, aka total sum scaling) a dataset to a constant k (usually taken to be 1). After closure the row sums of the dataset should sum to k.

**Usage**

```r
miniclo(c, k = 1)
```

**Arguments**

- `c`  
  dataset to be closed
- `k`  
  closure constant

**Value**

matrix (if c is a vector or matrix) or data.frame (if c is a data.frame)
Examples

```r
c <- matrix(c(1,2,3,1,2,3,1,2,3), nrow = 3, byrow=TRUE)
miniclo(c)
miniclo(c, k=2)
```

---

**name.balance**

_Name a balance (coordinate) based on taxonomy_

Description

For a given ILR balance (coordinate) assigns a name to the balance based on a provided taxonomy table. This is useful for interpretation of the balances.

Usage

```r
name.balance(tr, tax, coord, method = "voting", thresh = 0.95, return.votes = NULL)
```

Arguments

- **tr** an object of class `phylo`
- **tax** a matrix/data.frame of taxonomy, rownames should correspond to `tr$tip.labels` columns should be taxonomic levels (named) with increasing taxonomic resolution from left to right (e.g., Phylum to the left of Genus).
- **coord** the name of a balance/internal node on the tree (given as a string)
- **method** currently only `voting` implemented. See Details.
- **thresh** threshold for assignment of taxonomy to a given part of a balance (must be greater than 0.5 if `method="voting"`; see details).
- **return.votes** whether voting results by taxonomic level should be shown for `coord`. Note: this is helpful when `name.balance` does not return a clear winner, as may be the case when a given `coord` represents more than one taxonomic lineage. votes are returned as a list indexed by `colnames(tax)` Options include:
  - `NULL` (default) only returns the combined consensus name of the balance
  - `'up'` adds tallied votes for the `up` node to the output list
  - `'down'` adds tallied votes for the `down` node to the output list
  - `'self'` adds tallied votes for `coord` to the output list

Details

A bit of terminology:

- **coord** this is the same as the names of the balances which should be the same as the names of the internal nodes of `tr`
- `'up'` this is the child node of `coord` that is represented in the numerator of the `coord` balance.
- `'down'` this is the child node of `coord` that is represented in the denominator of the `coord` balance.

The method `voting` assigns the name of the each part of a balance (e.g., numerator and denominator / each child of `coord`) as follows:
1. First Subset tax to contain only descendent tips of the given child of coord
2. Second At the finest taxonomic (farthest right of tax) see if any one taxonomic label is present at or above thresh. If yes output that taxonomic label (at that taxonomic level) as the label for that child of coord. If no then move to coarser taxonomic level (leftward) and repeat.

Value
If $\text{return.votes=\text{null}}$ returns a string of the form (ex. 'Genus_Bacteroides/Phylum_Firmicutes'). Otherwise returns a list with the above string as 'name', see Arguments for show.votes for other optional returned items.

Examples
tr <- named_rtree(40)
tax <- data.frame(Kingdom=rep('A', 40),
                 Phylum=rep(c('B','C'), each=20),
                 Genus=c(sample(c('D','F'),20, replace=TRUE),
                          sample(c('G','H'), 20, replace=TRUE)))
rownames(tax) <- tr$tip.label
name.balance(tr, tax, 'n1')
name.balance(tr, tax, 'n34')
name.balance(tr,tax, 'n34', return.votes = c('up', 'down'))

named_rtree

Generate random tree with named internal nodes

Description
Internal nodes are named by numbering and adding the prefix ‘n’. This function is largely for use in examples throughout this package.

Usage
named_rtree(n)

Arguments

n
an integer giving the number of tips in the tree.

Value
An object of class "phylo"

Examples
named_rtree(5)
name_nodenumber_conversion

Convert between node/tip labels and integer node numbers

Description
Useful if you want to convert between node labels (c), tip labels (t) and the internal integer number that identifies that node (nn). Particularly for use with plotting libraries.

Usage

`nn.to.name(tr, x)`
`name.to.nn(tr, x)`

Arguments

`tr` object of type phylo
`x` vector of numerics or characters

Value

vector

Examples

```r
tr <- named_rtree(5)
name.to.nn(tr, 'n1')
name.to.nn(tr,c('n1','n2','t1'))
nn.to.name(tr, 1:9)
```

philr

Data transformation and driver of PhILR.

Description

This is the main function for building the phylogenetic ILR basis, calculating the weightings (of the parts and the ILR coordinates) and then transforming the data.

Usage

```r
philr(df, tree, sbp = NULL, part.weights = "uniform",
   ilr.weights = "uniform", return.all = FALSE)
```
Arguments

df matrix of data to be transformed (samples are rows, compositional parts are columns) - zero must be dealt with either with pseudocount, multiplicative replacement, or another method.
tree a phylo class tree object that is binary (see multi2di)
sbp (Optional) give a precomputed sbp matrix link(phylo2sbp) if you are going to build multiple ILR bases (e.g., with different weightings).
part.weights weightings for parts, can be a named vector with names corresponding to colnames(df) otherwise can be a string, options include:
'uniform' (default) uses the uniform reference measure
'gm.counts' geometric mean of parts of df
'anorm' aitchison norm of parts of df (after closure)
'anorm.x.gm.counts' 'anorm' times 'gm.counts'
'enorm' euclidean norm of parts of df (after closure)
'enorm.x.gm.counts' 'enorm' times 'gm.counts', often gives good results
ilr.weights weightings for the ILR coordinates can be a named vector with names corresponding to names of internal nodes of tree otherwise can be a string, options include:
'uniform' (default) no weighting of the ILR basis
'blw' sum of children's branch lengths
'blw.sqrt' square root of 'blw' option
'mean.descendants' sum of children's branch lengths PLUS the sum of each child's mean distance to its descendent tips
return.all return all computed parts (e.g., computed sign matrix(sbp), part weightings (codep), ilr weightings (codeilr.weights), contrast matrix (V)) as a list (default=FALSE) in addition to in addition to returning the transformed data (df.ilrp). If return.all==FALSE then only returns the transformed data (not in list format) If FALSE then just returns list containing df.ilrp.

Details

This is a utility function that pulls together a number of other functions in philr. The steps that are executed are as follows:

1. Create sbp (sign matrix) if not given
2. Create parts weightings if not given
3. Shift the dataset with respect to the new reference measure (e.g., part weightings)
4. Create the basis contrast matrix from the sign matrix and the reference measure
5. Transform the data based on the contrast matrix and the reference measure
6. Calculate the specified ILR weightings and multiply each balance by the corresponding weighting

Note for both the reference measure (part weightings) and the ILR weightings, specifying 'uniform' will give the same results as not weighting at all.

Parallelization is done through parallel package using type "FORK". Note parallelization is rarely needed, even for trees of upwards of 40,000 leaves.
phylo2sbp

Create Sequential Binary Partition from Phylogenetic Tree

Description

This function converts a binary phylogenetic tree to sequential binary partition to be used to then build an ILR basis for compositional metagenomic data.

Usage

phylo2sbp(tr)

Arguments

tr

a phylo tree object with n leaves

Details

The choice of orientation for a balance (i.e., which of the two descendant clades of an internal node is in the numerator or denominator of the log-ratio) is given by the default of the function phangorn::Children and that choice is used consistently throughout the philr package.

Value

a n by n-1 matrix of the sequential binary partition sign matrix

Author(s)

Justin Silverman

References

Schliep K.P. 2011. phangorn: phylogenetic analysis in R. Bioinformatics, 27(4) 592-593

Examples

tr <- named_rtree(5)
df <- t(rmultinom(10,100,c(.1,.6,.2,.3,.2))) + 0.65  # add a small pseudocount
colnames(df) <- tr$tip.label

philr(df, tr, part.weights="enorm.x.gm.counts",
ilr.weights='blw.sqrt', return.all=FALSE)
shiftp

See Also

philr

Examples

```
tr <- named_rtree(5)
phylo2sbp(tr)
```

Description

Shift must be applied before transformation

Usage

```
shiftp(x, p)
```

Arguments

- **x**: closed compositional data matrix (or vector)
- **p**: weights (should not be closed)

Value

Shifted data matrix `y` (no closure is applied) rows are samples, columns are parts

Author(s)

Justin Silverman & J. J. Egozcue

References

Examples

```
p <- seq(.1,1,by=.2)
c <- t(rmultinom(10,100,c(.1,.6,.2,.3,.2))) + 0.65  # add a small pseudocount
x <- minicl(c)
shiftp(x, p)
```
