Empirical Bayesian analysis of patterns of differential expression in count data.

Description

This package is intended to identify differential expression in high-throughput 'count' data, such as that derived from next-generation sequencing machines. We achieve this by empirical bayesian methods, first bootstrapping to estimate prior parameters from the data and then assessing posterior likelihoods of the models proposed.

Details

Package: baySeq
Type: Package
Version: 1.1.1
Date: 2009-16-05
License: GPL-3
LazyLoad: yes

To use the package, construct a countData object and use the functions documented in getPriors to empirically determine priors on the data. Then use the functions documented in getLikelihoods to establish posterior likelihoods for the models proposed. A few convenience functions, getTPs and topCounts are also included.

The package (optionally) makes use of the 'snow' package for parallelisation of computationally intensive functions. This is highly recommended for large data sets.

See the vignette for more details.

---

allModels

Function to generate all possible models for a countData object based on the replicate data.

Description

This function populates the '@groups' slot of the supplied countData object with all possible models for equivalence/non-equivalence of expression between replicate groups.

Usage

allModels(CD)
Arguments

CD       A countData object with a populated '@replicates' slot.

Details

Given a large number of different replicate groups, the total number of possible models listed in the
'@groups' slot rises exponentially. This function will attempt to list them all. The use of consensus
priors (see getPriors) is recommended if the number of models is high.

Value

A countData with populated '@groups' slot.

Examples

# load test data
data(simData)

# Create a (countData) object from test data, supposing that there are
# multiple experimental groups present.

replicates <- c("simA", "simA", "simB", "simC", "simD", "simE", "simE", "simF", "simG")
CD <- new("countData", data = simData, replicates = replicates)
CD <- allModels(CD)

# The total number of models generated is high.
length(CD@groups)

Description

The countData class is used to define summaries of count data and establishing prior and posterior
parameters on distributions defined upon the count data.

Slots

Objects of these class contain the following components:
baySeq-classes

BaySeq classes are used for analyzing RNA-seq data. They include:

- **data**: Count data (matrix).
- **replicates**: The replicate structure of the data. Stored as a factor, but can be given in any form.
- **groups**: Group (model) structure to test on the data (list).
- **annotation**: Annotation data for each count (data.frame).
- **priorType**: Character string describing the type of prior information available in slot 'priors'.
- **priors**: Prior parameter information. Calculated by the functions described in getPriors.
- **posteriors**: Estimated (log)-posterior likelihoods for each group (matrix). Calculated by the functions described in getLikelihoods.
- **estProps**: Estimated proportion of tags belonging to each group (numeric). Calculated by the functions described in getLikelihoods.
- **nullPosts**: If calculated, the posterior likelihoods for the data having no true expression of any kind.
- **seglens**: Lengths of segments containing the counts described in data. A matrix, but may be initialised with a vector.

### Details

The seglens slot describes, for each row of the data object, the length of the 'segment' that contains the number of counts described by that row. For example, if we are looking at the number of hits matching genes, the seglens object would consist of transcript lengths. Exceptionally, we may want to use different segment lengths for different samples and so the slot takes the form of a matrix. If the matrix has only one column, it is duplicated for all samples. Otherwise, it should have the same number of columns as the '@data' slot. If the slot is the empty matrix, then it is assumed that all segments have the same length.

### Methods

The standard methods 'new', 'dim', '[', 'show' and 'rbind' have been defined for these classes. The methods 'groups', 'groups<-', 'replicates', 'replicates<-', 'libsizes' and 'libsizes<-’ have also been defined in order to access and modify these slots, and their use is recommended.

### Author(s)

Thomas J. Hardcastle

### Examples

```r
#load test data
data(simData)

# Create a 'countData' object from test data.
groups <- list(NDE = c(1,1,1,1,1,1,1,1), DE = c(1,1,1,1,2,2,2,2))
CD <- new("countData", data = simData, replicates = replicates, groups = groups)

#estimate library sizes for countData object
libsizes(CD) <- getLibsizes(CD)

CD[1:10,]
dim(CD)
```
bimodalSeparator

A function that, given a numeric vector, finds the value which splits the data into two sets of minimal total variance using Otsu’s method.

Description

This function takes a numeric vector and finds the value which splits the data into two sets of minimal total variance, weighted by the size of subsets (Otsu’s method). It is principally intended to be a quick and easy way of separating bimodally distributed data.

Usage

bimodalSeparator(x, weights = NULL, minperc = 0.1, elbow = NULL)

Arguments

x
A numeric vector containing the data to be split.

weights
Possible weightings on the values in x for calculating the variance.

minperc
The required minimum size of each of the two subsets, expressed as a percentage of the total size. See Details.

elbow
If set, finds the ‘left’ or ‘right’ elbow of variance, instead of the minimum; defaults to NULL. See Details.

Details

This function is intended to give a quick and easy way of splitting bimodally distributed data. Where there are large outliers in the data, it may be that the value which minimises the variance does not split the bimodal data but isolates the outliers. The ‘minperc’ parameter can be used to ensure that each subset of the split data will be of some minimum size, avoiding the outlier problem.

If ‘elbow = NULL’ (the default) then the split occurs at the value that minimises the variance, x0. If ‘elbow = left’ then we attempt to find the elbow point to the left of the value that minimises the variance, if ‘elbow = right’ then we find the elbow point to the right of the value that minimises the variance. Elbow points are found by drawing a line from the first point (for the left elbow) or the last point (for the right elbow) to x0, and finding the location on the curve of summed variances which maximises the distance to that line.

Value

Numeric value which splits the data.

Author(s)

Thomas J. Hardcastle

Examples

bimodalSeparator(c(rnorm(200, mean = c(5,7), sd = 1)))
### CDPost

A `countData` object derived from data file `simData` with estimated likelihoods of differential expression.

**Description**

This `countData` object is derived from the data set `simData` and contains the estimated likelihoods of differential expression. This data set is intended to be used to speed the processing of the examples.

**Usage**

CDPost

**Format**

A `countData` object.

**Source**

Simulation.

**References**

### CDPriors

A `countData` object derived from data file `simData` with estimated priors.

**Description**

This `countData` object is derived from the data set `simData` and contains the estimated priors. This data set is intended to be used to speed the processing of the examples.

**Usage**

CDPriors

**Format**

A `countData` object.

**Source**

Simulation.

**References**

densityFunction-class

Class "densityFunction"

Description

This function fills the `@densityFunction` slot of a ‘countData’ object. It defines the distribution used to estimate posterior likelihoods, and associated values used in these calculations.

Objects from the Class

Objects can be created by calls of the form `new("densityFunction", ...)`. 

Slots

description: A description of the distribution defined.
density: A "function", defining the likelihood of a data array given observed data and hyperparameters.
initiatingValues: A "list" of functions (may be supplied as numerics) that define initial values of numeric prior discovery.
equalOverReplicates: A "logical", describing which of the hyperparameters are equally marginally distributed over all groups, and which are not.
lower: A "function", required to define the lower limit of optimisation in the case where only one hyperparameter is *not* equally marginally distributed over all groups.
upper: A "function", required to define the upper limit of optimisation, as for ‘lower’, above.
stratifyFunction: An optional "function", used to stratify the data for more accurate prior estimation.
stratifyBreaks: An optional "numeric", used to define the number of strata in a stratification.
nullFunction: An optional "function" on the hyperparameters, used to generate a one-dimensional distribution which can be partitioned to identify ‘null’ data.
orderingFunction: An optional "function" for ordering the data between groups of a model.
modifyNullPriors: An optional "function" for modifying the priors for the ‘null’ data.

Methods

No methods defined with class "densityFunction" in the signature.

Author(s)

Thomas J. Hardcastle

Examples

```
showClass("densityFunction")
```
densityFunctions

Lists all currently available densityFunctions.

Description
The densityFunction objects define the distribution and various other parameters used to analyse the data stored in a countData object.

Usage
densityFunctions()

Value
Character string giving names of available densityFunction objects.

Author(s)
Thomas J. Hardcastle

References

densityFunction

getLibsizes

Estimates library scaling factors (library sizes) for count data.

Description
This function estimates the library scaling factors that should be used for either a 'countData', or a matrix of counts and replicate information.

Usage
getLibsizes(cD, data, replicates, subset = NULL, estimationType = c("quantile", "total", "edgeR"), quantile = 0.75, ...)

Arguments
cD A countData object.
data A matrix of count values. Ignored if 'cD' is given.
replicates A replicate structure for the data given in 'data'. Ignored if 'cD' is given.
subset A numerical vector indicating the rows of the 'countData' object that should be used to estimate library scaling factors.
estimationType One of 'quantile', 'total', or 'edgeR'. Partial matching is allowed. See Details.
quantile A value between 0 and 1 indicating the level of trimming that should take place. See Details.
... Additional parameters to be passed to the 'edgeR' calcNormFactors function.
getLikelihoods

Details

This function estimates the library scaling factors (surrogates for library size) in one of several ways, depending on the `estimationType` argument. 'total' will give the library sizes by summing all counts in each sample. 'quantile' will give a library scaling factor by the method of Bullard et al (Bioinformatics 2010), summing all counts in each sample whose value below the qth quantile of non-zero counts for that sample. 'edgeR' uses the Trimmed Mean of M-values (TMM) method of Robinson & Oshlack (Genome Biology, 2010) via the 'edgeR' `calcNormFactors` function; other options are available through this function.

If a `countData` object 'cD' is given, the library sizes will be inferred from this. Alternatively, a matrix of count values (columns are libraries) and a replicate structure (a vector defining which samples belong to which replicate group) can be given.

Value

If a `countData` object is given, an identical object will be returned with updated library sizes. If only the data and replicate structure are given, a numerical vector of library sizes (scaling factors) for each library in the data will be returned.

CD <- new("countData", data = simData, replicates = replicates, groups = groups)
libsizes(CD) <- getLibsizes(CD)

getLikelihoods

Finds posterior likelihoods for each count or paired count as belonging to some model.

Description

These functions calculate posterior probabilities for each of the rows in a `countData` object belonging to each of the models specified in the 'groups' slot.

Usage

getLikelihoods.NB(cD, prs, pET = "BIC", marginalise = FALSE, subset = NULL, priorSubset = NULL, bootStraps = 1, conv = 1e-4, nullData = FALSE, returnAll = FALSE, returnPD = FALSE, verbose = TRUE, discardSampling = FALSE, cl, ...) getLikelihoods.BB(cD, prs, pET = "BIC", marginalise = FALSE, subset =...
getLikelihoods

NULL, priorSubset = NULL, bootStraps = 1, conv = 1e-04, nullData = FALSE, returnAll = FALSE, returnPD = FALSE, verbose = TRUE, discardSampling = FALSE, cl, ...)
getLikelihoods(cD, prs, pET = "BIC", marginalise = FALSE, subset = NULL, priorSubset = NULL, bootStraps = 1, bsNullOnly = TRUE, conv = 1e-4, nullData = FALSE, weightByLocLikelihoods = TRUE, modelPriorSets = list(), modelPriorValues = list(), returnAll = FALSE, returnPD = FALSE, verbose = TRUE, discardSampling = FALSE, modelLikes = TRUE, c1 = NULL, tempFile = NULL, largeness = 1e+08)

Arguments

cD An object of type countData, or descending from this class.

prs (Initial) prior probabilities for each of the groups in the ‘cD’ object. Should sum to 1, unless nullData is TRUE, in which case it should sum to less than 1.

pET What type of prior re-estimation should be attempted? Defaults to "BIC"; "none" and "iteratively" are also available.

marginalise Should an attempt be made to numerically marginalise over a prior distribution iteratively estimated from the posterior distribution? Defaults to FALSE, as in general offers little performance gain and increases computational cost considerably.

subset Numeric vector giving the subset of counts for which posterior likelihoods should be estimated.

priorSubset Numeric vector giving the subset of counts which may be used to estimate prior probabilities on each of the groups. See Details.

bootStraps How many iterations of bootstrapping should be used in the (re)estimation of priors in the negative binomial method.

bsNullOnly If TRUE (default, bootstrap hyper-parameters based on the likelihood of the null model and its inverse only; otherwise, on the likelihood of all models.

conv If not null, bootstrapping iterations will cease if the mean squared difference between posterior likelihoods of consecutive bootstraps drops below this value.

nullData If TRUE, looks for segments or counts with no true expression. See Details.

weightByLocLikelihoods If a locLikelihoods slot is present in the ‘cD’ object, and nullData = TRUE, then the initial weighting on nulls will be determined from the locLikelihoods slot. Defaults to TRUE.

modelPriorSets If given, a list object, which defines subsets of the data for which different priors on the different models might be expected. See Details.

modelPriorValues If given, a list object which defines priors on the different models. See Details.

returnAll If TRUE, and bootStraps > 1, then instead of returning a single countData object, the function returns a list of countData objects; one for each bootstrap. Largely used for debugging purposes.

returnPD If TRUE, then the function returns the (log) likelihoods of the data given the models, rather than the posterior (log) likelihoods of the models given the data. Not recommended for general use.

verbose Should status messages be displayed? Defaults to TRUE.
If TRUE, discards information about which data rows are sampled to generate prior information. May slightly degrade the results but reduce computational time required. Defaults to FALSE.

If TRUE (default), returns likelihoods for each model. If FALSE, returns likelihoods for each hyper-parameter, from which the posterior joint distribution on hyper-parameters can be inferred.

A SNOW cluster object.

Temporary file prefix for saving data likelihoods. Primarily for debugging purposes at this stage. Defaults to NULL, in which case no temporary data are saved.

The maximum size over which data likelihoods are calculated. Objects larger than this are split. This is most useful in combination with the saving of temporary files in the case of excessively large analyses.

Any additional information to be passed to the 'getLikelihoods' function by the now deprecated functions.

These functions estimate, under the assumption of various distributions, the (log) posterior likelihoods that each count belongs to a group defined by the @group slot of the input object. The posterior likelihoods are stored on the natural log scale in the @posteriors slot of the countData object generated by this function. This is because the posterior likelihoods are calculated in this form, and ordering of the counts is better done on these log-likelihoods than on the likelihoods.

If 'pET = "none"' then no attempt is made to re-estimate the prior likelihoods given in the 'prs' variable. However, if 'pET = "BIC"', then the function will attempt to estimate the prior likelihoods by using the Bayesian Information Criterion to identify the proportion of the data best explained by each model and taking these proportions as prior. Alternatively, an iterative re-estimation of priors is possible ('pET = "iteratively"'), in which an initial estimate for the prior likelihoods of the models is used to calculated the posteriors and then the priors are updated by taking the mean of the posterior likelihoods for each model across all data. This often works well, particularly if the 'BIC' method is used (see Hardcastle & Kelly 2010 for details). However, if the data are sufficiently non-independent, this approach may substantially mis-estimate the true priors. If it is possible to select a representative subset of the data by setting the variable 'subsetPriors' that is sufficiently independent, then better estimates may be acquired.

In certain circumstances, it may be expected that certain subsets of the data are likely to behave differently to others; for example, if a set of genes are expected in advance to be differentially expressed, while the majority of the data are not. In this case, it may be advantageous (in terms of improving false discovery rates) to specify these different subsets in the modelPriorSets variable. However, care should be taken downstream to avoid confirmation bias.

Filtering the data may be extremely advantageous in reducing run time. This can be done by passing a numeric vector to 'subset' defining a subset of the data for which posterior likelihoods are required.

See Hardcastle & Kelly (2010) for a definition of the negative binomial methods.

A 'cluster' object is strongly recommended in order to parallelise the estimation of posterior likelihoods, particularly for the negative binomial method. However, passing NULL to the cl variable will allow the functions to run in non-parallel mode.

The 'getLikelihoods.NB' and 'getLikelihoods.BB' functions are now deprecated and will soon be removed.
Value

A `countData` object.

getPosteriors

An internal function in the baySeq package for calculating posterior likelihoods given likelihoods of the data.

Description

For likelihoods of the data given a set of models, this function calculates the posterior likelihoods of the models given the data. An internal function of baySeq, which should not in general be called by the user.

Usage

getPosteriors(ps, prs, pET = "none", marginalise = FALSE, groups, priorSubset = NULL, maxit = 100, 1e-5, eqOverRep = NULL, cl = cl)

Arguments

ps A matrix containing likelihoods of the data for each count (rows) under each model (columns).
prs (Initial) prior probabilities for each of the models.
pET What type of prior re-estimation should be attempted? Defaults to "none"; "BIC" and "iteratively" are also available.
marginalise Should an attempt be made to numerically marginalise over a prior distribution iteratively estimated from the posterior distribution? Defaults to FALSE, as in general offers little performance gain and increases computational cost considerably.
groups Group structure from which likelihoods in 'ps' were defined.
priorSubset If 'estimatePriors = TRUE', what subset of the data should be used to re-estimate the priors? Defaults to NULL, implying all data will be used.
maxit What is the maximum number of iterations that should be tried if we are bootstrapping prior probabilities from the data?
accuracy How small should the difference in estimated priors be before we stop bootstrapping.

cl Parallelisation cluster object.
An internal function, that will not in general be called by the user. It takes the log-likelihoods of the data given the models being tested and returns the posterior likelihoods of the models.

The function may attempt to estimate the prior likelihoods either by using the Bayesian Information Criterion (\texttt{pET = \textquoteleft\textquoteleft BIC\textquoteright\textquoteleft\textquoteright}) to identify the proportion of the data best explained by each model and taking these proportions as prior. Alternatively, an iterative re-estimation of priors is possible (\texttt{pET = \\textquoteleft\textquoteleft iteratively\textquoteright\textquoteleft\textquoteright}, in which an initial estimate for the prior likelihoods of the models is used to calculated the posteriors and then the priors are updated by taking the mean of the posterior likelihoods for each model across all data.

A list containing posteriors: estimated posterior likelihoods of the model for each count (log-scale) priors: estimated (or given) prior probabilities of the model

Thomas J. Hardcastle

pps$priors
pps$posteriors[1:10,]
getPriors

Estimates prior parameters for the underlying distributions of 'count' data.

**Description**

These functions estimate, via maximum likelihood methods, the parameters of the underlying distributions specified in the 'densityFunction' slot of the countData object. A special case is maintained for historical reasons; getPriors.NB estimates parameters for a negative binomial distribution using quasi-maximum-likelihood methods.

**Usage**

```r
getPriors(cD, samplesize = 1e5, samplingSubset = NULL, consensus = FALSE, cl, verbose = TRUE)
getPriors.NB(cD, samplesize = 1e5, samplingSubset = NULL, equalDispersions = TRUE, estimation = "QL", verbose = TRUE, zeroML = FALSE, consensus = FALSE, cl, ...)
```

**Arguments**

- `cD`: A `countData` or `pairedData` object.
- `samplesize`: How large a sample should be taken in estimating the priors?
- `samplingSubset`: If given, the priors will be sampled only from the subset specified.
- `consensus`: If TRUE, creates a consensus distribution rather than a separate distribution for each member of the groups structure in the 'cD' object. See Details.
- `cl`: A SNOW cluster object.
- `verbose`: Should status messages be displayed? Defaults to TRUE.
- `equalDispersions`: Should we assume equal dispersions of data across all groups in the 'cD' object? Defaults to TRUE; see Details.
- `estimation`: Defaults to "QL", indicating quasi-likelihood estimation of priors. Currently, the only other possibilities are "ML", a maximum-likelihood method, and "edgeR", the moderated dispersion estimates produced by the 'edgeR' package. See Details.
- `zeroML`: Should parameters from zero data (rows that within a group are all zeros) be estimated using maximum likelihood methods (which will result in zeros in the parameters? See Details.
- `...`: Additional parameters to be passed to the `estimateTagwiseDisp` function if 'estimation = "edgeR"'.

**Details**

These functions empirically estimate prior parameters for the distributions used in estimating posterior likelihoods of each count belonging to a particular group. For unpaired count data, the distributions on the data are assumed to be negative binomial. For paired count data, the distributions on the data are assumed to be beta-binomial.

For priors estimated for the negative binomial methods, three options are available. Differences in the options focus on the way in which the dispersion is estimated for the data. In simulation studies,
quasi-likelihood methods (‘estimation = "QL"’) performed best and so these are used by default. Alternatives are maximum-likelihood methods (‘estimation = "ML"’), and the ‘edgeR’ packages moderated dispersion estimates (‘estimation = "edgeR"’).

The priors estimated for the negative binomial methods (‘getPriors.NB’) may assume that the dispersion of data for a given row is identical for all group structures defined in ‘cD@groups’ (‘equalDispersions = TRUE’). Alternatively, the dispersions may be estimated individually for each group structure (‘equalDispersions = FALSE’). Unless there is a strong reason for believing that the data are differently dispersed between groups, ‘equalDispersions = TRUE’ is recommended. If ‘estimation = "edgeR"’ then this parameter is ignored and dispersion is assumed identical for all group structures.

If all counts in a given row for a given group are zero, then maximum and quasi-likelihood estimation methods will result in a zero parameter for the mean. In analyses where segment length is a factor, this makes it hard to differentiate between (for example) a region which contains no reads but is only ten bases long and one which likewise contains no reads but is ten megabases long. If ‘zeroML’ is FALSE, therefore, the dispersion is set to 1 and the mean estimated as the value that leaves the likelihood of zero data at fifty percent.

If ‘consensus = TRUE’, then a consensus distribution is created and used for each group in the ‘cD’ object. This allows faster computation of the priors and likelihoods, but with some degradation of accuracy.

A ‘cluster’ object is recommended in order to estimate the priors for the negative binomial distribution. Passing NULL to this variable will cause the function to run in non-parallel mode.

Value

A countData object.

**getTPs**  
*Gets the number of true positives in the top n counts selected by ranked posterior likelihoods*

**Description**

If the true positives are known, this function will return a vector, the ith member of which gives the number of true positives identified if the top i counts, based on estimated posterior likelihoods, are chosen.

**Usage**

getTPs(cD, group, decreasing = TRUE, TPs)

**Arguments**

- `cD`  
  *countData* object, containing posterior likelihoods for each group.
- `group`  
  Which group should we give the counts for? See Details.
- `decreasing`  
  Ordering on posterior likelihoods.
- `TPs`  
  Known true positives.

**Details**

In the rare (or simulated) cases where the true positives are known, this function will calculate the number of true positives selected at any cutoff.

The ‘group’ can be defined either as the number of the element in ‘cD@groups’ or as a string which will be partially matched to the names of the ‘cD@groups’ elements. If group = NULL, then the function looks at the posterior likelihoods that the data have no true differential expression (if calculated).

**Value**

A vector, the ith member of which gives the number of true positives identified if the top i counts are chosen.

countData

Examples

# See vignette for more examples.
# We load in a `countData` object containing the estimated posterior
# likelihoods of expression (see `getLikelihoods`).
data(CDPost)

# If the first hundred rows in the `simData` matrix are known to be
# truly differentially expressed (the second hypothesis defined in the
# `groups` list) then we find the number of true positives for the top n
# genes selected as the nth member of
getTPs(CDPost, group = "DE", decreasing = TRUE, TPs = 1:100)

makeOrderings

Construct orderings for count data given a model structure and an
ordering function.

Description

Given a model structure as defined in the `@groups` slot of a countData object containing more
than one group, it is often possible to define an ordering on the groups for a given genomic event.
To take a simple example, if the average expression of a gene is higher in sample set A then in
sample set B, then we might impose an ordering A>B.

Usage

makeOrderings(cD, orderingFunction)

Arguments

cD
A countData object, or a descendant thereof.

orderingFunction
A function defining the orderings. If not given, will be taken from the `@densityFunction` slot of `cD`. See Details, and examples below.

Details

The orderingFunction takes `dat` and `observables` as arguments. `dat` is equivalent to the `@data`
slot of the `cD` object, and `observables` the combined data in the `@sampleObservables`, `@rowObservables` and `@cellObservables` slots.
Value

A `countData` with populated ‘@orderings’ slot.

Examples

```r
# load test data
data(simData)

# Create a countData object from test data
groups <- list(NDE = c(1,1,1,1,1,1,1,1), DE = c(1,1,1,1,2,2,2,2))
CD <- new("countData", data = simData, replicates = replicates, groups = groups)

# order on expression normalised for library size (scaling factor) and gene length
libsizes(CD) <- getLibsizes(CD)

CD <- makeOrderings(CD, orderingFunction = function(dat, observables) dat / observables$libsizes)

# orderings calculated for DE group
head(CD@orderings)

# load test (paired) data
data(pairData)

data(pairData)

# create a countData object from paired data
pairCD <- new("countData", data = list(pairData[,1:4], pairData[,5:8]),
             replicates = c(1,1,2,2), groups = list(NDE = c(1,1,1,1), DE = c(1,1,2,2)),
             densityFunction = bbDensity)
libsizes(pairCD) <- getLibsizes(pairCD)

# order on (log-)ratio of pairs, with fudge-factor on zeros.
pairCD <- makeOrderings(pairCD, orderingFunction = function(dat, observables) {
  data <- dat / observables$libsizes
  adjmin <- min(dat[dat > 0]) / 10
  log(data[,1] + adjmin) - log(data[,2] + adjmin)
})

# orderings calculated for DE group
head(pairCD@orderings)
```
marginaliseEqual

Computes marginal likelihoods that two replicate groups are equal.

Description

In cases where multiple models are simultaneously evaluated in the `getLikelihoods` function, the posterior likelihoods for each model in which two conditions are equivalent can be summed to give the marginal likelihood of equivalence for all biomolecular events (i.e., data rows).

Usage

`marginaliseEqual(cD, r1, r2)`

Arguments

- `cD` A `countData` object with evaluated posterior likelihoods in the `@posteriors` slot.
- `r1` A defined group name to identify in the `@groups` slot of the `countData` object `cD`.
- `r2` A defined group name to identify in the `@groups` slot of the `countData` object `cD`.

Value

A vector of marginal posterior likelihoods defining the probability that the two group identifiers are equal for each row of the data.

Author(s)

Thomas J. Hardcastle

See Also

- `allModels`
- `marginalisePairwise`

Examples

```r
# load test data
data(simData)

# Create a (countData) object from test data, supposing that there are
# multiple experimental groups present.
CD <- new("countData", data = simData, replicates = replicates)
CD <- allModels(CD)

# The total number of models generated is high.
length(CD@groups)

# Priors and likelihoods acquired through standard means.
```
marginalisePairwise

Computes marginal likelihoods that two replicate groups differ, in a particular direction.

Description

In cases where multiple models are simultaneously evaluated in the 'getLikelihoods' function, the posterior likelihoods for each model in which one condition is greater than another can be summed to give the marginal likelihood of (directed) difference for all biomolecular events (i.e., data rows).

Usage

marginalisePairwise(cD, greaterThan, lessThan)

Arguments

cD A countData object with evaluated posterior likelihoods in the '@posteriors' slot.
greaterThan A defined group name (or vector of group names) to identify in the '@groups' slot of the countData object 'cD'; the function will identify all models in which these groups are equivalent and greater than that defined in the 'lessThan' variable.
lessThan A defined group name (or vector of group names) to identify in the '@groups' slot of the countData object 'cD'; the function will identify all models in which these groups are equivalent and less than that defined in the 'greaterThan' variable.

Value

A vector of marginal posterior likelihoods defining the probability that the two group identifiers are (directionally) different for each row of the data.

Author(s)

Thomas J. Hardcastle

See Also

allModels marginaliseEqual
Examples

# load test data
data(simData)

# Create a (countData) object from test data, supposing that there are
# multiple experimental groups present.
replicates <- c("simA", "simA", "simB", "simC", "simD", "simE", "simE", "simF", "simG")
CD <- new("countData", data = simData, replicates = replicates)
CD <- allModels(CD)

# The total number of models generated is high.
length(CD@groups)

# Priors and likelihoods acquired through standard means.
## Not run: CD <- getPriors(CD, cl = cl)
## Not run: CD <- getLikelihoods(CD, cl = cl)

# Marginal likelihood that 'simA' condition is greater than 'simD' group
# for each row of the data.
## Not run: marginalisePairwise(CD, "simA", "simD")

methObservables  Generation of intermediate values in likelihood estimation for methylation data.

Description

Estimating prior and posterior values for methylation data that account for non-conversion rates is a time-consuming process. Significant increases in speed can be made by calculating in advance sets of data that will be re-used at several points of these analyses. This function populates the '@cellObservables' slot of a 'countData' object that contains a 'nonconversion' object in the '@sampleObservables' slot.

Usage

methObservables(mD)

Arguments

mD  A countData object, or descendant, which contains a numeric vector 'nonconversion' in the '@sampleObservables' slot.

Value

A countData object with the '@cellObservables' slot populated with temporary values useful in the faster calculation of likelihoods.

Author(s)

Thomas J. Hardcastle
mobAnnotation

Annotation data for a set of small RNA loci derived from sequencing of grafts of Arabidopsis thaliana intended for differential expression analyses.

Description

This data set is a data.frame (‘mobAnnotation’) describing three thousand small RNA loci identified in a set of Arabidopsis grafting experiments.

The data acquired through sequencing for these loci is found in data file ‘mobData’.

Usage

mobAnnotation

Format

A data.frame defining chromosome and position of the sRNA loci.

Source

Illumina sequencing.

References

See Also

mobData

mobData

Data from a set of small RNA sequencing experiments carried out on grafts of Arabidopsis thaliana intended for differential expression analyses.

Description

This data set is a matrix (‘mobData’) of counts acquired for three thousand small RNA loci from a set of Arabidopsis grafting experiments. Three different biological conditions exist within these data; one in which a Dicer 2,3,4 triple mutant shoot is grafted onto a Dicer 2,3,4 triple mutant root (SL236 and SL260), one in which a wild-type shoot is grafted onto a wild-type root (SL239 and SL240), and one in which a wild-type shoot is grafted onto a Dicer 2,3,4 triple mutant root (SL237 and SL238). Dicer 2,3,4 is required for the production of 22nt and 24nt small RNAs, as well as some 21nt ones. Consequently, if we detect differentially expressed sRNA loci in the root stock of the grafts, we can make inferences about the mobility of small RNAs.

The annotation of the loci from which these data derive is in data file ‘mobAnnotation’.
**pairData**

**Usage**

`mobData`

**Format**

A matrix of which each of the six columns represents a sample, and each row an sRNA locus (acquired by sequencing).

**Source**

Illumina sequencing.

**References**

**See Also**

`mobAnnotation`

---

**Description**

This data set is a matrix (`pairData`) of simulated counts from a set of high-throughput sequencing data from a paired experimental design. The first four columns of data are to be paired with the second four columns of data respectively. The first two paired samples form one replicate group, the second two paired samples form another replicate group. The first hundred rows of the data are truly differentially expressed between replicate groups, the second hundred are differentially expressed between pairs, the remainder have no differential expression.

It is simulated according to a set of Poisson distributions whose parameters for each row are determined by a beta distribution on the relative proportions of data in each pairing.

**Usage**

`pairData`

**Format**

A matrix of which each of the eight columns represents a sample, and each row some discrete data (acquired by sequencing).

**Source**

Simulation.
plotMA.CD

'MA'-plot for count data.

Description

This function creates an MA-plot from two sets of samples. For those data where the log-ratio is infinite (because in one set of sample data all observed counts are zero), we plot instead the log-values of the other group.

Usage

plotMA.CD(cD, samplesA, samplesB, normaliseData = TRUE, scale = NULL, xlab = "A", ylab = "M", ...)

Arguments

cD

A countData object.
samplesA

Either a character vector, identifying sample set A by either replicate name or sample name, or a numerical vector giving the columns of data in the 'countData' object that forms sample set A. See Details.
samplesB

Either a character vector, identifying sample set B by either replicate name or sample name, or a numerical vector giving the columns of data in the 'countData' object that forms sample set B. See Details.

normaliseData

Should the data be normalised by library size before computing log-ratios? Defaults to TRUE.
scale

If given, defines the scale on which the log-ratios will be plotted. Defaults to NULL, implying that the scale will be calculated by the function.
xlab

Label for the X-axis. Defaults to "A".
ylab

Label for the Y-axis. Defaults to "M".

...

Any other parameters to be passed to the plot function.

Details

The samples sets can be identified either by a numeric vector which specifies the columns of data from the countData object 'cD', or by a character vector. If a character vector is used, the members of the character vector will first be searched for in the @replicates slot of the 'cD' object. Any members of the vector not found in the replicates slot, will be searched for in the column names of the @data slot of the 'cD' object. Different classes of vector can be used for 'samplesA' and 'samplesB', as shown in the example below.

Value

Plotting function.

Author(s)

Thomas J. Hardcastle
plotNullPrior

See Also
countData

Examples

data(simData)
groups <- list(NDE = c(1,1,1,1,1,1,1,1), DE = c(1,1,1,1,2,2,2,2))
CD <- new("countData", data = simData, replicates = replicates, groups = groups)

#estimate library sizes for countData object
libsizes(CD) <- getLibsizes(CD)

#MA-plot comparing replicate groups
plotMA.CD(CD, samplesA = "simA", samplesB = 6:10)

plotNullPrior

Plots distribution of null function and shows the threshold separator.

Description

In sequencing expression of various genomic events, it is not uncommon to find a subset of genomic events that are qualitatively different from the remainder of the data. Thus, for some function of the estimated priors, we may observe bimodality or long tails which correlate to this subset.

Usage

plotNullPrior(cD, ...)

Arguments

cD A countData object with a `@nullFunction` slot in its `@densityFunction`.

... Additional arguments to be passed to `plot`

Value

Invisibly, the numeric value of the threshold.

Author(s)

Thomas J. Hardcastle
plotPosteriors  

Plots the posterior likelihoods estimated for a `countData` object against the log-ratios observed between two sets of sample data.

**Description**

This function plots the posterior likelihoods estimated for a `countData` object against the log-ratios observed between two sets of sample data. For those data where the log-ratio is infinite (because in one set of sample data all observed counts are zero), we plot instead the log-values of the other group.

**Usage**

```r
plotPosteriors(cD, group, samplesA, samplesB, ...)
```

**Arguments**

- `cD`: A `countData` object, for which posterior likelihoods have been estimated (see `getPosteriors`).
- `group`: From which group (as defined in the `cD@groups` slot) should posterior likelihoods be shown? Can be defined either as the number of the element in `cD@groups` or as a string which will be partially matched to the names of the `cD@groups` elements.
- `samplesA`: A numerical vector giving the columns of data in the `countData` object that forms sample set A.
- `samplesB`: A numerical vector giving the columns of data in the `countData` object that forms sample set B.
- `...`: Any other parameters to be passed to the `plot` function.

**Value**

Plotting function.

**Author(s)**

Thomas J. Hardcastle

**See Also**

`getPosteriors`

**Examples**

```r
# We load in a `countData` object containing the estimated posterior
# likelihoods of expression (see `getLikelihoods`).

data(CDPost)

plotPosteriors(CDPost, group = "DE", samplesA = 1:5, samplesB = 6:10)
```
# equivalent to plotPosteriors(CDPost, group = 2, samplesA = 1:5, samplesB = 6:10)

plotPriors

Plots the density of the log values estimated for the mean rate in the prior data for the Negative Binomial approach to detecting differential expression

Description

This function plots the density of the log values estimated for the mean rate in the data used to estimate a prior distribution for data under the assumption of a Negative Binomial distribution. This function is useful for looking for bimodality of the distributions, and thus determining whether we should try and identify data with no true expression.

Usage

plotPriors(cD, group, par = 1)

Arguments

cD

countData object, for which priors have been estimated using the assumption of a Negative Binomial distribution (see getPriors.NB).

group

Which group should we plot the priors for? In general, should be the group that defines non-differentially expressed data. Can be defined either as the number of the element in 'cD@groups' or as a string which will be partially matched to the names of the 'cD@groups' elements.

par

The parameter of the prior that will be plotted.

Details

If the plot of the data appears bimodal, then it may be sensible to try and look for data with no true expression by using the option nullPosts = TRUE in getLikelihoods.NB.

Value

Plotting function.

Author(s)

Thomas J. Hardcastle

getPriors.NB, getLikelihoods.NB

Examples

# We load in a `countData` object containing the estimated priors (see `getPriors`).
data(CDPriors)

plotPriors(CDPriors, group = "NDE", par = 1)
selectTop

*Selects the top genomic events, based on posterior likelihoods, from a* `countData` *object.*

**Description**

This function subsets a countData object by selecting those events that best (or least) represent a model, based on the posterior likelihoods estimated for that model and some threshold. Selection can be done for a specific model (and ordering of the data under that model) or for all models (and all orderings).

**Usage**

```r
selectTop(cD, group, ordering, orderings = TRUE, decreasing = TRUE, number = 10, likelihood, FDR, FWER, posteriors)
```

**Arguments**

- `cD`: A `countData` object, with a populated `@posteriors` slot (unless ‘posteriors’ is specified; see below).
- `group`: Optionally, the model of interest, as defined in the `@groups` slot of the `countData` object. If unspecified, subsets for all models will be returned as a list.
- `ordering`: If `group` is specified, a particular ordering of the data based on that group can also be specified.
- `orderings`: If no group is specified, should the selection of models also be split by the orderings of the data under the models? Defaults to TRUE.
- `decreasing`: If FALSE, considers the data with the lowest posterior likelihoods, rather than the greatest (i.e., selects those data least likely to conform to a particular model.
- `number`: If given, selects the top ‘number’ of genomic events for each model (and optionally, ordering). Ignored if another selection criteria is chosen, unless this criteria would return no values.
- `likelihood`: If given, selects all genomic events for a given model (and optionally, ordering) with posterior likelihood exceeding this value.
- `FDR`: If given, selects all genomic events for a given model (and optionally, ordering) with false discovery rate below this value. Ignored if likelihood is specified.
- `FWER`: If given, selects all genomic events for a given model (and optionally, ordering) with family-wise error rate below this value. Ignored if likelihood or FDR is specified.
- `posteriors`: If given, a vector of log-posterior likelihoods to use instead of those in the `@posteriors` slot of the ‘cD’ object.

**Value**

Either a single `countData` object (if ‘group’ is specified), or a named list of `countData` objects.

**Author(s)**

Thomas J. Hardcastle
### simData

**Simulated data for testing the baySeq package methods**

#### Description

This data set is a matrix ("simData") of simulated counts from a simple pairwise expression analysis. It is simulated according to a negative binomial distribution with varying parameters for each row. The first hundred rows of the data are truly differentially expressed, the remainder have no differential expression.

#### Usage

```r
simData
```

#### Format

A matrix of which each of the ten columns represents a sample, and each row some discrete data (acquired by sequencing).

#### Source

Simulation.

#### References

**summarisePosteriors**

*Summarises expected number of genomic events given the calculated posterior likelihoods of a countData object.*

### Description

Given posterior likelihoods for each model, we can calculate the expected number of genomic events corresponding to each model (and to each ordering within each model) by summing the posterior likelihoods.

### Usage

```r
summarisePosteriors(cD, orderings = TRUE)
```

### Arguments

- `cD` A `countData` object.
- `orderings` Indicates whether models should be split by orderings of the data under the model (defaults to TRUE).

### Value

Numeric vector of expected number of genomic events belonging to each model (optionally, split by orderings).

### Author(s)

Thomas J. Hardcastle

### See Also

topCounts, selectTop

### Examples

```r
# We load in a 'countData' object containing the estimated posterior
# likelihoods of expression (see `getLikelihoods`).
data(CDPost)

# summarise the expected number of genomic events in each category
summarisePosteriors(CDPost)
```
topCounts

Get the top counts corresponding to some group from a `countData` object

Description

Takes posterior likelihoods and returns the counts with highest (or lowest) likelihood of association with a given group.

Usage

topCounts(cD, group, ordering, decreasing = TRUE, number = 10, likelihood, FDR, FWER, normaliseData = FALSE, posteriors)

Arguments

cD  `countData` object, containing posterior likelihoods for each group (unless ‘posteriors’ is specified; see below).

group  Which group should we give the counts for? See Details.

ordering  If specified, restricts the analysis to a particular ordering on the group.

decreasing  Ordering on posterior likelihoods.

number  How many results should be returned?

likelihood  If given, ignores ‘number’ and returns all results above a certain likelihood (and FDR, and FWER, if given).

FDR  If given, ignores ‘number’ and returns all results with an FDR lower than this threshold (and likelihood, and FWER, if given).

FWER  If given, ignores ‘number’ and returns all results with an FWER lower than this threshold (and likelihood, and FDR, if given).

normaliseData  Should the displayed counts be normalised? See details. Defaults to FALSE.

posteriors  If given, a vector of log-posterior likelihoods to use instead of those in the ‘@posteriors’ slot of the ‘cD’ object.

Details

The argument ‘group’ can be specified either as a number, giving the index of an element in the `cD@groups` list, or as a character string identifying an element by name. Partial matching is allowed.

If group = NULL, then the function looks at the posterior likelihoods that the data have no true differential expression (if calculated).

If a `countData` object is given, the returned dataframe will contain either the raw counts for that object, or (if ‘normaliseData = TRUE’ the counts normalised by library size.

Value

A dataframe of the top counts associated with some model (group), described by annotation drawn from the ‘@annotation’ slot of the ‘cD’ object and the raw data from the ‘@data’ slot, together with the posterior likelihoods and false discovery rates.
zimData

Simulated data for testing the baySeq package methods

Description

This data set is a matrix (`zimData`) of zero-inflated simulated counts from a simple pairwise expression analysis. It is simulated according to a negative binomial distribution with varying parameters for each row, and with zero-inflation applied to each row. The first hundred rows of the data are truly differentially expressed, the remainder have no differential expression.

Usage

zimData

Format

A matrix of which each of the ten columns represents a sample, and each row some discrete data (acquired by sequencing).
