01.Introduction	<i>Introduction to the LIMMA Package</i>
-----------------	--

---

## Description

LIMMA is a library for the analysis of gene expression microarray data, especially the use of linear models for analysing designed experiments and the assessment of differential expression. LIMMA provides the ability to analyse comparisons between many RNA targets simultaneously in arbitrary complicated designed experiments. Empirical Bayesian methods are used to provide stable results even when the number of arrays is small. The linear model and differential expression functions apply to all gene expression technologies, including microarrays, RNA-seq and quantitative PCR.

## Details

There are three types of documentation available:

1. The *LIMMA User's Guide* can be reached through the "User Guides and Package Vignettes" links at the top of the LIMMA contents page. The function `limmaUsersGuide` gives the file location of the User's Guide.
2. An overview of limma functions grouped by purpose is contained in the numbered chapters at the foot of the LIMMA package index page, of which this page is the first.
3. The LIMMA contents page gives an alphabetical index of detailed help topics.

The function `changeLog` displays the record of changes to the package.

02.Classes

*Topic: Classes Defined by this Package*

---

## Description

This package defines the following data classes.

- RGList** A class used to store raw intensities as they are read in from an image analysis output file, usually by `read.maimages`.
- MAList** Intensities converted to M-values and A-values, i.e., to with-spot and whole-spot contrasts on the log-scale. Usually created from an **RGList** using `MA.RG` or `normalizeWithinArrays`. Objects of this class contain one row for each spot. There may be more than one spot and therefore more than one row for each probe.
- EListRaw** A class to store raw intensities for one-channel microarray data. May or may not be background corrected. Usually created by `read.maimages`.
- EList** A class to store normalized log<sub>2</sub> expression values for one-channel microarray data. Usually created by `normalizeBetweenArrays`.
- MArrayLM** Store the result of fitting gene-wise linear models to the normalized intensities or log-ratios. Usually created by `lmFit`. Objects of this class normally contain only one row for each unique probe.
- TestResults** Store the results of testing a set of contrasts equal to zero for each probe. Usually created by `decideTests`. Objects of this class normally contain one row for each unique probe.

All these data classes obey many analogies with matrices. In the case of **RGList**, **MAList**, **EListRaw** and **EList**, rows correspond to spots or probes and columns to arrays. In the case of **MArrayLM**, rows correspond to unique probes and the columns to parameters or contrasts. The functions `summary`, `dim`, `length`, `ncol`, `nrow`, `dimnames`, `rownames`, `colnames` have methods for these classes. Objects

of any of these classes may be [subsetting](#). Multiple data objects may be [combined](#) by rows (to add extra probes) or by columns (to add extra arrays).

Furthermore all of these classes may be coerced to actually be of class `matrix` using `as.matrix`, although this entails loss of information. Fitted model objects of class `MArrayLM` can be coerced to class `data.frame` using `as.data.frame`.

The first three classes belong to the virtual class `LargeDataObject`. A `show` method is defined for `LargeDataObjects` which uses the utility function `printHead`.

03.ReadingData

*Topic: Reading Microarray Data from Files*

---

### Description

This help page gives an overview of LIMMA functions used to read data from files.

### Reading Target Information

The function `readTargets` is designed to help with organizing information about which RNA sample is hybridized to each channel on each array and which files store information for each array.

### Reading Intensity Data

The first step in a microarray data analysis is to read into R the intensity data for each array provided by an image analysis program. This is done using the function `read.maimages`.

`read.maimages` optionally constructs quality weights for each spot using quality functions listed in [QualityWeights](#).

If the data is two-color, then `read.maimages` produces an `RGList` object. If the data is one-color (single channel) then an `EListRaw` object is produced. In either case, `read.maimages` stores only the information required from each image analysis output file. `read.maimages` uses utility functions `removeExt`, `read.imagene` and `read.columns`. There are also a series of utility functions which read the header information from image output files including `readGPRHeader`, `readImaGeneHeader` and `readGenericHeader`.

`read.ilmn` reads probe or gene summary profile files from Illumina BeadChips, and produces an `EListRaw` object.

`read.idat` reads Illumina files in IDAT format, and produces an `EListRaw` object. `detectionPValues` can be used to add detection p-values.

The function `as.MAList` can be used to convert a `marrayNorm` object to an `MAList` object if the data was read and normalized using the `marray` and `marrayNorm` packages.

## Reading the Gene List

Most image analysis software programs provide gene IDs as part of the intensity output files, for example GenePix, Imagen and the Stanford Microarray Database do this. In other cases the probe ID and annotation information may be in a separate file. The most common format for the probe annotation file is the GenePix Array List (GAL) file format. The function `readGAL` reads information from a GAL file and produces a data frame with standard column names.

The function `getLayout` extracts from the GAL-file data frame the print layout information for a spotted array. The functions `gridr`, `gridc`, `spotr` and `spotc` use the extracted layout to compute grid positions and spot positions within each grid for each spot. The function `printorder` calculates the printorder, plate number and plate row and column position for each spot given information about the printing process. The utility function `getSpacing` converts character strings specifying spacings of duplicate spots to numeric values.

The Australian Genome Research Facility in Australia often produces GAL files with composite probe IDs or names consisting of multiple strings separated by a delimiter. These can be separated into name and annotation information using `strsplit2`.

If each probe is printed more than once of the arrays in a regular pattern, then `uniquegenelist` will remove duplicate names from the gal-file or gene list.

## Identifying Control Spots

The functions `readSpotTypes` and `controlStatus` assist with separating control spots from ordinary genes in the analysis and data exploration.

## Manipulating Data Objects

`cbind`, `rbind`, `merge` allow different `RGList` or `MAList` objects to be combined. `cbind` combines data from different arrays assuming the layout of the arrays to be the same. `merge` can combine data even when the order of the probes on the arrays has changed. `merge` uses utility function `makeUnique`.

## Description

This page deals with background correction methods provided by the `backgroundCorrect`, `kooperberg` or `neqc` functions. Microarray data is typically background corrected by one of these functions before normalization and other downstream analysis.

`backgroundCorrect` works on matrices, `EListRaw` or `RGList` objects, and calls `backgroundCorrect.matrix`.

The `movingmin` method of `backgroundCorrect` uses utility functions `ma3x3.matrix` and `ma3x3.spottedarray`.

The `normexp` method of `backgroundCorrect` uses utility functions `normexp.fit` and `normexp.signal`. `kooperberg` is a Bayesian background correction tool designed specifically for two-color GenePix data. It is computationally intensive and requires several additional columns from the GenePix data files. These can be read in using `read.maimages` and specifying the `other.columns` argument. `neqc` is for single-color data. It performs `normexp` background correction and quantile normalization using control probes. It uses utility functions `normexp.fit.control` and `normexp.signal`. If `robust=TRUE`, then `normexp.fit.control` uses the function `huber` in the `MASS` package.

05.Normalization

*Topic: Normalization of Microarray Data*

---

**Description**

This page gives an overview of the LIMMA functions available to normalize data from single-channel or two-colour microarrays. Smyth and Speed (2003) give an overview of the normalization techniques implemented in the functions for two-colour arrays.

Usually data from spotted microarrays will be normalized using `normalizeWithinArrays`. A minority of data will also be normalized using `normalizeBetweenArrays` if diagnostic plots suggest a difference in scale between the arrays.

In rare circumstances, data might be normalized using `normalizeForPrintorder` before using `normalizeWithinArrays`.

All the normalization routines take account of spot quality weights which might be set in the data objects. The weights can be temporarily modified using `modifyWeights` to, for example, remove ratio control spots from the normalization process.

If one is planning analysis of single-channel information from the microarrays rather than analysis of differential expression based on log-ratios, then the data should be normalized using a single channel-normalization technique. Single channel normalization uses further options of the `normalizeBetweenArrays` function. For more details see the [LIMMA User's Guide](#) which includes a section on single-channel normalization.

`normalizeWithinArrays` uses utility functions `MA.RG`, `loessFit` and `normalizeRobustSpline`.

`normalizeBetweenArrays` is the main normalization function for one-channel arrays, as well as an optional function for two-colour arrays. `normalizeBetweenArrays` uses utility functions `normalizeMedianAbsValues`, `normalizeMedianAbsValues`, `normalizeQuantiles` and `normalizeCyclicLoess`, none of which need to be called directly by users.

`neqc` is a between array normalization function customized for Illumina BeadChips.

The function `normalizeVSN` is also provided as a interface to the `vsn` package. It performs variance stabilizing normalization, an algorithm which includes background correction, within and between normalization together, and therefore doesn't fit into the paradigm of the other methods.

`removeBatchEffect` can be used to remove a batch effect, associated with hybridization time or some other technical variable, prior to unsupervised analysis.

06.LinearModels

*Topic: Linear Models for Microarrays***Description**

This page gives an overview of the LIMMA functions available to fit linear models and to interpret the results. This page covers models for two color arrays in terms of log-ratios or for single-channel arrays in terms of log-intensities. If you wish to fit models to the individual channel log-intensities from two colour arrays, see [07.SingleChannel](#).

The core of this package is the fitting of gene-wise linear models to microarray data. The basic idea is to estimate log-ratios between two or more target RNA samples simultaneously. See the LIMMA User's Guide for several case studies.

**Fitting Models**

The main function for model fitting is `lmFit`. This is recommended interface for most users. `lmFit` produces a fitted model object of class `MArrayLM` containing coefficients, standard errors and residual standard errors for each gene. `lmFit` calls one of the following three functions to do the actual computations:

`lm.series` Straightforward least squares fitting of a linear model for each gene.

`mrlm` An alternative to `lm.series` using robust regression as implemented by the `r1m` function in the MASS package.

`gls.series` Generalized least squares taking into account correlations between duplicate spots (i.e., replicate spots on the same array) or related arrays. The function `duplicateCorrelation` is used to estimate the inter-duplicate or inter-block correlation before using `gls.series`.

All the functions which fit linear models use `link{getEAW}` to extract data from microarray data objects, and `unwrapdups` which provides an unified method for handling duplicate spots.

**Forming the Design Matrix**

`lmFit` has two main arguments, the expression data and the design matrix. The design matrix is essentially an indicator matrix which specifies which target RNA samples were applied to each channel on each array. There is considerable freedom in choosing the design matrix - there is always more than one choice which is correct provided it is interpreted correctly.

Design matrices for Affymetrix or single-color arrays can be created using the function `model.matrix` which is part of the R base package. The function `modelMatrix` is provided to assist with creation of an appropriate design matrix for two-color microarray experiments. For direct two-color designs, without a common reference, the design matrix often needs to be created by hand.

### Making Comparisons of Interest

Once a linear model has been fit using an appropriate design matrix, the command `makeContrasts` may be used to form a contrast matrix to make comparisons of interest. The fit and the contrast matrix are used by `contrasts.fit` to compute fold changes and t-statistics for the contrasts of interest. This is a way to compute all possible pairwise comparisons between treatments for example in an experiment which compares many treatments to a common reference.

### Assessing Differential Expression

After fitting a linear model, the standard errors are moderated using a simple empirical Bayes model using `eBayes` or `treat`. `ebayes` is an older version of `eBayes`. A moderated t-statistic and a log-odds of differential expression is computed for each contrast for each gene. `treat` tests whether log-fold-changes are greater than a threshold rather than merely different to zero.

`eBayes` and `eBayes` use internal functions `squeezeVar`, `fitFDist`, `tmixture.matrix` and `tmixture.vector`.

The function `zscoreT` is sometimes used for computing z-score equivalents for t-statistics so as to place t-statistics with different degrees of freedom on the same scale. `zscoreGamma` is used the same way with standard deviations instead of t-statistics. These functions are for research purposes rather than for routine use.

### Summarizing Model Fits

After the above steps the results may be displayed or further processed using:

`topTable` or `topTable` Presents a list of the genes most likely to be differentially expressed for a given contrast.

`topTableF` Presents a list of the genes most likely to be differentially expressed for a given set of contrasts.

`volcanoplot` Volcano plot of fold change versus the B-statistic for any fitted coefficient.

`plotlines` Plots fitted coefficients or log-intensity values for time-course data.

`genas` Estimates and plots biological correlation between two coefficients.

`write.fit` Writes an `MArrayLM` object to a file. Note that if `fit` is an `MArrayLM` object, either `write.fit` or `write.table` can be used to write the results to a delimited text file.

For multiple testing functions which operate on linear model fits, see [08.Tests](#).

### Model Selection

`selectModel` provides a means to choose between alternative linear models using AIC or BIC information criteria.

---

[07.SingleChannel](#)

*Topic: Individual Channel Analysis of Two-Color Microarrays*

---

**Description**

This page gives an overview of the LIMMA functions fit linear models to two-color microarray data in terms of the log-intensities rather than log-ratios.

The function [intraspotCorrelation](#) estimates the intra-spot correlation between the two channels. The regression function [lmscFit](#) takes the correlation as an argument and fits linear models to the two-color data in terms of the individual log-intensities. The output of [lmscFit](#) is an `MArrayLM` object just the same as from [lmFit](#), so inference proceeds in the same way as for log-ratios once the linear model is fitted. See [06.LinearModels](#).

The function [targetsA2C](#) converts two-color format target data frames to single channel format, i.e., converts from array-per-line to channel-per-line, to facilitate the formulation of the design matrix.

---

[08.Tests](#)

*Topic: Hypothesis Testing for Linear Models*

---

**Description**

LIMMA provides a number of functions for multiple testing across both contrasts and genes. The starting point is an `MArrayLM` object, called `fit` say, resulting from fitting a linear model and running `eBayes` and, optionally, `contrasts.fit`. See [06.LinearModels](#) or [07.SingleChannel](#) for details.

**Multiple testing across genes and contrasts**

The key function is [decideTests](#). This function writes an object of class `TestResults`, which is basically a matrix of  $-1$ ,  $0$  or  $1$  elements, of the same dimension as `fit$coefficients`, indicating whether each coefficient is significantly different from zero. A number of different multiple testing strategies are provided. The function calls other functions [classifyTestsF](#), [classifyTestsP](#) and [classifyTestsT](#) which implement particular strategies. The function [FStat](#) provides an alternative interface to [classifyTestsF](#) to extract only the overall moderated F-statistic.

[selectModel](#) chooses between linear models for each probe using AIC or BIC criteria. This is an alternative to hypothesis testing and can choose between non-nested models.

A number of other functions are provided to display the results of `decideTests`. The functions `heatDiagram` (or the older version `heatdiagram`) displays the results in a heat-map style display. This allows visual comparison of the results across many different conditions in the linear model.

The functions `vennCounts` and `vennDiagram` provide Venn diagram style summaries of the results.

Summary and show method exists for objects of class `TestResults`.

The results from `decideTests` can also be included when the results of a linear model fit are written to a file using `write.fit`.

### Gene Set Tests

Competitive gene set testing for an individual gene set is provided by `wilcoxGST` or `geneSetTest`, which permute genes. The gene set can be displayed using `barcodeplot`.

Self-contained gene set testing for an individual set is provided by `roast`, which uses rotation technology, analogous to permuting arrays.

Gene set enrichment analysis for a large database of gene sets is provided by `romer`. `topRomer` is used to rank results from `romer`.

The functions `alias2Symbol`, `alias2SymbolTable` and `alias2SymbolUsingNCBI` are provided to help match gene sets with microarray probes by way of official gene symbols.

### Global Tests

The function `genas` can test for associations between two contrasts in a linear model.

Given a set of p-values, the function `propTrueNull` can be used to estimate the proportion of true null hypotheses.

When evaluating test procedures with simulated or known results, the utility function `auROC` can be used to compute the area under the Receiver Operating Curve for the test results for a given probe.

### Description

This page gives an overview of the LIMMA functions available for microarray quality assessment and diagnostic plots.

This package provides an `anova` method which is designed for assessing the quality of an array series or of a normalization method. It is not designed to assess differential expression of individual genes. `anova` uses utility functions `bwss` and `bwss.matrix`.

The function `arrayWeights` estimates the empirical reliability of each array following a linear model fit.

Diagnostic plots can be produced by

[imageplot](#) Produces a spatial picture of any spot-specific measure from an array image. If the log-ratios are plotted, then this produces an in-silico representation of the well known false-color TIFF image of an array. [imageplot3by2](#) will write imageplots to files, six plots to a page.

[plotFB](#) Plots foreground versus background log-intensities.

[plotMD](#) Mean-difference plots. Very versatile plot. For two color arrays, this plots the M-values vs A-values. For single channel technologies, this plots one column of log-expression values vs the average of the other columns. For fitted model objects, this plots a log-fold-change versus average log-expression. [mdplot](#) can also be useful for comparing two one-channel microarrays.

[plotMA](#) MA-plots, essentially the same as mean-difference plots. [plotMA3by2](#) will write MA-plots to files, six plots to a page.

[plotWithHighlights](#) Scatterplots with highlights. This is the underlying engine for [plotMD](#) and [plotMA](#).

[plotPrintTipLoess](#) Produces a grid of MA-plots, one for each print-tip group on an array, together with the corresponding loess curve. Intended to help visualize print-tip loess normalization.

[plotPrintorder](#) For an array, produces a scatter plot of log-ratios or log-intensities by print order.

[plotDensities](#) Individual channel densities for one or more arrays. An essential plot to accompany between array normalization, especially quantile normalization.

[plotMDS](#) Multidimensional scaling plot for a set of arrays. Useful for visualizing the relationship between the set of samples.

[plotSA](#) Sigma vs A plot. After a linear model is fitted, this checks constancy of the variance with respect to intensity level.

[plotPrintTipLoess](#) uses utility functions [gridr](#) and [gridc](#). [plotDensities](#) uses utility function [RG.MA](#).

### Description

This page gives an overview of the LIMMA functions for gene set testing and pathway analysis.

[roast](#) Self-contained gene set testing for one set.

[mroast](#) Self-contained gene set testing for many sets.

- fry** Fast approximation to mroast, especially useful when heteroscedasticity of genes can be ignored.
- camera** Competitive gene set testing.
- romer and topRomer** Gene set enrichment analysis.
- ids2indices** Convert gene sets consisting of vectors of gene identifiers into a list of indices suitable for use in the above functions.
- alias2Symbol and alias2SymbolTable** Convert gene symbols or aliases to current official symbols.
- geneSetTest or wilcoxGST** Simple gene set testing based on gene or probe permutation.
- barcodeplot** Enrichment plot of a gene set.
- goana and topGO** Gene ontology over-representation analysis of gene lists using Entrez Gene IDs. goana can work directly on a fitted model object or on one or more lists of genes.
- kegga and topKEGG** KEGG pathway over-representation analysis of gene lists using Entrez Gene IDs. kegga can work directly on a fitted model object or on one or more lists of genes.

11.RNAseq

*Topic: Analysis of RNA-seq Data***Description**

This page gives an overview of LIMMA functions to analyze RNA-seq data.

- voom** Transform RNA-seq or ChIP-seq counts to log counts per million (log-cpm) with associated precision weights. After this transformation, RNA-seq or ChIP-seq data can be analyzed using the same functions as would be used for microarray data.
- voomWithQualityWeights** Combines the functionality of voom and arrayWeights.
- diffSplice** Test for differential exon usage between experimental conditions.
- topSplice** Show a data.frame of top results from diffSplice.
- plotSplice** Plot results from diffSplice.
- plotExons** Plot logFC for individual exons for a given gene.

---

 alias2Symbol

*Convert Gene Aliases to Official Gene Symbols*

---

**Description**

Maps gene alias names to official gene symbols.

**Usage**

```
alias2Symbol(alias, species = "Hs", expand.symbols = FALSE)
alias2SymbolTable(alias, species = "Hs")
alias2SymbolUsingNCBI(alias, gene.info.file,
                      required.columns = c("GeneID", "Symbol", "description"))
```

**Arguments**

<code>alias</code>	character vector of gene aliases
<code>species</code>	character string specifying the species. Possible values include "Hs" (human), "Mm" (mouse), "Rn" (rat), "Dm" (fly) or "Pt" (chimpanzee), but other values are possible if the corresponding organism package is available.
<code>expand.symbols</code>	logical. This affects those elements of <code>alias</code> that are the official gene symbol for one gene and also an alias for another gene. If <code>FALSE</code> , then these elements will just return themselves. If <code>TRUE</code> , then all the genes for which they are aliases will also be returned.
<code>gene.info.file</code>	either the name of a gene information file downloaded from the NCBI or a <code>data.frame</code> resulting from reading such a file.
<code>required.columns</code>	character vector of columns from the gene information file that are required in the output.

**Details**

Aliases are mapped via NCBI Entrez Gene identity numbers using Bioconductor organism packages.

`alias2Symbol` maps a set of aliases to a set of symbols, without necessarily preserving order. The output vector may be longer or shorter than the original vector, because some aliases might not be found and some aliases may map to more than one symbol.

`alias2SymbolTable` returns of vector of the same length as the vector of aliases. If an alias maps to more than one symbol, then the one with the lowest Entrez ID number is returned. If an alias can't be mapped, then `NA` is returned.

`species` can be any character string `XX` for which an organism package `org.XX.eg.db` exists and is installed. The only requirement of the organism package is that it contains objects `org.XX.egALIAS2EG`

and `org.XX.egSYMBOL` linking the aliases and symbols to Entrez Gene Ids. At the time of writing, the following organism packages are available from Bioconductor 3.6:

Package	Species
org.Ag.eg.db	Anopheles
org.Bt.eg.db	Bovine
org.Ce.eg.db	Worm
org.Cf.eg.db	Canine
org.Dm.eg.db	Fly
org.Dr.eg.db	Zebrafish
org.EcK12.eg.db	E coli strain K12
org.EcSakai.eg.db	E coli strain Sakai
org.Gg.eg.db	Chicken
org.Hs.eg.db	Human
org.Mm.eg.db	Mouse
org.Mmu.eg.db	Rhesus
org.Pt.eg.db	Chimp
org.Rn.eg.db	Rat
org.Ss.eg.db	Pig
org.Xl.eg.db	Xenopus

`alias2SymbolUsingNCBI` is analogous to `alias2SymbolTable` but uses a gene-info file from NCBI instead of a Bioconductor organism package. It also gives the option of returning multiple columns from the gene-info file. NCBI gene-info files can be downloaded from [ftp://ftp.ncbi.nlm.nih.gov/gene/DATA/GENE\\_INFO](ftp://ftp.ncbi.nlm.nih.gov/gene/DATA/GENE_INFO). For example, the human file is [ftp://ftp.ncbi.nlm.nih.gov/gene/DATA/GENE\\_INFO/Mammalia/Homo\\_sapiens.gene\\_info.gz](ftp://ftp.ncbi.nlm.nih.gov/gene/DATA/GENE_INFO/Mammalia/Homo_sapiens.gene_info.gz) and the mouse file is [ftp://ftp.ncbi.nlm.nih.gov/gene/DATA/GENE\\_INFO/Mammalia/Mus\\_musculus.gene\\_info.gz](ftp://ftp.ncbi.nlm.nih.gov/gene/DATA/GENE_INFO/Mammalia/Mus_musculus.gene_info.gz).

### Value

`alias2Symbol` and `alias2SymbolTable` produce a character vector of gene symbols. `alias2SymbolTable` returns a vector of the same length and order as `alias`, including NA values where no gene symbol was found. `alias2Symbol` returns an unordered vector that may be longer or shorter than `alias`.

`alias2SymbolUsingNCBI` returns a data.frame with rows corresponding to the entries of `alias` and columns as specified by `required.columns`.

### Author(s)

Gordon Smyth and Yifang Hu

### See Also

This function is often used to assist gene set testing, see [10.GeneSetTests](#).

### Examples

```
alias2Symbol(c("PUMA", "NOXA", "BIM"), species="Hs")
alias2Symbol("RS1", expand=TRUE)
```

---

anova.MAList-method    *ANOVA Table - method*

---

### Description

Analysis of variance method for objects of class `MAList`. Produces an ANOVA table useful for quality assessment by decomposing between and within gene sums of squares for a series of replicate arrays. This method produces a single ANOVA Table rather than one for each gene and is not used to identify differentially expressed genes.

### Usage

```
anova(object, design=NULL, ndups=2, ...)
```

### Arguments

`object` object of class `MAList`. Missing values in the M-values are not allowed.

`design` numeric vector or single-column matrix containing the design matrix for linear model. The length of the vector or the number of rows of the matrix should agree with the number of columns of M.

`ndups` number of duplicate spots. Each gene is printed `ndups` times in adjacent spots on each array.

... other arguments are not used

### Details

This function aids in quality assessment of microarray data and in the comparison of normalization methodologies. It applies only to replicated two-color experiments in which all the arrays are hybridized with the same RNA targets, possibly with dye-swaps, so the design matrix should have only one column. The function has not been heavily used and is somewhat experimental.

### Value

An object of class `anova` containing rows for between genes, between arrays, gene x array interaction, and between duplicate with array sums of squares. Variance components are estimated for each source of variation.

### Note

This function does not give valid results in the presence of missing M-values.

### Author(s)

Gordon Smyth

arrayWeights

*Array Quality Weights***Description**

Estimates relative quality weights for each array in a multi-array experiment.

**Usage**

```
arrayWeights(object, design = NULL, weights = NULL, var.design = NULL,
             method = "genebygene", maxiter = 50, tol = 1e-10, trace=FALSE)
arrayWeightsSimple(object, design = NULL,
                  maxiter = 100, tol = 1e-6, maxratio = 100, trace=FALSE)
```

**Arguments**

object	object of class <code>numeric</code> , <code>matrix</code> , <code>MAList</code> , <code>marrayNorm</code> , <code>ExpressionSet</code> or <code>PLMset</code> containing log-expression-ratios or log-expression values for a series of microarrays. Most contain at least 3 columns and at least as many rows as columns.
design	the design matrix of the microarray experiment, with rows corresponding to arrays and columns to coefficients to be estimated. Defaults to the unit vector meaning that the arrays are treated as replicates.
weights	optional numeric matrix containing prior weights for each spot.
var.design	design matrix for the variance model. Defaults to the sample-specific model whereby each sample has a distinct variance when <code>NULL</code> .
method	character string specifying the estimating algorithm to be used. Choices are "genebygene" and "reml".
maxiter	maximum number of iterations allowed.
tol	convergence tolerance.
maxratio	maximum ratio between largest and smallest weights before iteration stops
trace	logical variable. If true then output diagnostic information at each iteration of the "reml" algorithm, or at every 1000th iteration of the "genebygene" algorithm.

**Details**

The relative reliability of each array is estimated by measuring how well the expression values for that array follow the linear model.

The method is described in Ritchie et al (2006). A heteroscedastic model is fitted to the expression values for each gene by calling the function `lm.wfit`. The dispersion model is fitted to the squared residuals from the mean fit, and is set up to have array specific coefficients, which are updated in either full REML scoring iterations, or using an efficient gene-by-gene update algorithm. The final estimates of these array variances are converted to weights.

The data object `object` is interpreted as for `lmFit`. In particular, the arguments `design` and `weights` will be extracted from the data object if available and do not normally need to be set explicitly in the call; if any of these are set in the call then they will over-ride the slots or components in the data object.

`arrayWeightsSimple` is a fast version of `arrayWeights` with `method="reml"`, no prior weights and no missing values.

**Value**

A vector of array weights.

## End(Not run)
```

---

arrayWeightsQuick      *Array Quality Weights*

---

**Description**

Estimates relative quality weights for each array in a multi-array experiment with replication.

**Usage**

```
arrayWeightsQuick(y, fit)
```

**Arguments**

y	the data object used to estimate fit. Can be of any class which can be coerced to matrix, including matrix, MAList, marrayNorm or ExpressionSet.
fit	MArrayLM fitted model object

**Details**

Estimates the relative reliability of each array by measuring how well the expression values for that array follow the linear model.

This is a quick and dirty version of [arrayWeights](#).

**Value**

Numeric vector of weights of length `ncol(fit)`.

**Author(s)**

Gordon Smyth

## End(Not run)
```

---

as.data.frame

*Turn a Microarray Linear Model Object into a Dataframe*

---

**Description**

Turn a `MArrayLM` object into a `data.frame`.

**Usage**

```
## S3 method for class 'MArrayLM'
as.data.frame(x, row.names = NULL, optional = FALSE, ...)
```

**Arguments**

<code>x</code>	an object of class <code>MArrayLM</code>
<code>row.names</code>	NULL or a character vector giving the row names for the data frame. Missing values are not allowed.
<code>optional</code>	logical. If TRUE, setting row names and converting column names (to syntactic names) is optional.
<code>...</code>	additional arguments to be passed to or from methods.

**Details**

This method combines all the components of `x` which have a row for each probe on the array into a `data.frame`.

**Value**

A `data.frame`.

**Author(s)**

Gordon Smyth

**See Also**

[as.data.frame](#) in the base package.

[02.Classes](#) gives an overview of data classes used in LIMMA. [06.LinearModels](#) gives an overview of linear model functions in LIMMA.

---

`as.MAList`*Convert marrayNorm Object to an MAList Object*

---

**Description**

Convert `marrayNorm` Object to an `MAList` Object

**Usage**

```
as.MAList(object)
```

**Arguments**

`object`            an `marrayNorm` object

**Details**

The `marrayNorm` class is defined in the `marray` package. This function converts a normalized two color microarray data object created by the `marray` package into the corresponding `limma` data object.

Note that such conversion is not necessary to access the `limma` linear modelling functions, because `lmFit` will operate on a `marrayNorm` data object directly.

**Value**

Object of class `MAList`

**Author(s)**

Gordon Smyth

**See Also**

[02.Classes](#) gives an overview of all the classes defined by this package.

The `marrayNorm` class is defined in the `marray` package.

---

as.matrix

*Turn a Microarray Data Object into a Matrix*

---

### Description

Turn a microarray data object into a numeric matrix by extracting the expression values.

### Usage

```
## S3 method for class 'MAList'
as.matrix(x,...)
```

### Arguments

x                    an object of class RGList, MAList, EList, MArrayLM, marrayNorm, PLMset, ExpressionSet, LumiBatch or vsn.  
 ...                    additional arguments, not used for these methods.

### Details

These methods extract the matrix of log-ratios, for MAList or marrayNorm objects, or the matrix of expression values for other expression objects such as EList or ExpressionSet. For MArrayLM objects, the matrix of fitted coefficients is extracted.

These methods involve loss of information, so the original data object is not recoverable.

### Value

A numeric matrix.

### Author(s)

Gordon Smyth

### See Also

[as.matrix](#) in the base package or [exprs](#) in the Biobase package.  
[02.Classes](#) gives an overview of data classes used in LIMMA.

---

asMatrixWeights

*asMatrixWeights*

---

### Description

Convert probe-weights or array-weights to a matrix of weights.

### Usage

```
asMatrixWeights(weights, dim)
```

**Arguments**

weights	numeric matrix of weights, rows corresponding to probes and columns to arrays. Or vector of probe weights. Or vector of array weights.
dim	numeric dimension vector of length 2, i.e., the number of probes and the number of arrays.

**Details**

This function converts a vector or probe-weights or a vector of array-weights to a matrix of the correct size. Probe-weights are repeated across rows while array-weights are repeated down the columns. If weights has length equal to the number of probes, it is assumed to contain probe-weights. If it has length equal to the number of arrays, it is assumed to contain array-weights. If the number of probes is equal to the number of arrays, then weights is assumed to contain array-weights if it is a row-vector of the correct size, i.e., if it is a matrix with one row.

This function is used internally by the linear model fitting functions in limma.

**Value**

Numeric matrix of dimension dim.

**Author(s)**

Gordon Smyth

**See Also**

[modifyWeights](#).

An overview of functions in LIMMA used for fitting linear models is given in [06.LinearModels](#).

**Examples**

```
asMatrixWeights(1:3,c(4,3))
asMatrixWeights(1:4,c(4,3))
```

---

 auROC

*Area Under Receiver Operating Curve*

---

**Description**

Compute exact area under the ROC for empirical data.

**Usage**

```
auROC(truth, stat=NULL)
```

**Arguments**

truth	logical vector, or numeric vector of 0s and 1s, indicating whether each case is a true positive.
stat	numeric vector containing test statistics used to rank cases, from largest to smallest. If NULL, then truth is assumed to be already sorted in decreasing test statistic order.

**Details**

A receiver operating curve (ROC) is a plot of sensitivity (true positive rate) versus 1-specificity (false positive rate) for a statistical test or binary classifier. The area under the ROC is a well accepted measure of test performance. It is equivalent to the probability that a randomly chosen pair of cases is correctly ranked.

Here we consider a test statistic `stat`, with larger values being more significant, and a vector `truth` indicating whether the alternative hypothesis is in fact true. `truth==TRUE` or `truth==1` indicates a true discovery and `truth=FALSE` or `truth=0` indicates a false discovery. Correct ranking here means that `truth[i]` is greater than or equal to `truth[j]` when `stat[i]` is greater than `stat[j]`. The function computes the exact area under the empirical ROC curve defined by `truth` when ordered by `stat`.

If `stat` contains ties, then `auROC` returns the average area under the ROC for all possible orderings of `truth` for tied `stat` values.

The area under the curve is undefined if `truth` is all TRUE or all FALSE or if `truth` or `stat` contain missing values.

**Value**

Numeric value between 0 and 1 giving area under the curve, 1 being perfect and 0 being the minimum.

**Author(s)**

Gordon Smyth

**Examples**

```
auROC(c(1,1,0,0,0))
truth <- rbinom(30,size=1,prob=0.2)
stat <- rchisq(30,df=2)
auROC(truth,stat)
```

---

avearrays

*Average Over Replicate Arrays*

---

**Description**

Condense a microarray data object so that technical replicate arrays are replaced with (weighted) averages.

**Usage**

```
## Default S3 method:
avearrays(x, ID=colnames(x), weights=NULL)
## S3 method for class 'MList'
avearrays(x, ID=colnames(x), weights=x$weights)
## S3 method for class 'EList'
avearrays(x, ID=colnames(x), weights=x$weights)
```

**Arguments**

x	a matrix-like object, usually a matrix, MAList or EList object.
ID	sample identifier.
weights	numeric matrix of non-negative weights

**Details**

A new data object is computed in which technical replicate arrays are replaced by their (weighted) averages.

For an MAList object, the components M and A are both averaged in this way, as are weights and any matrices found in object\$other.

EList objects are similar, except that the E component is averaged instead of M and A.

If x is of mode "character", then the replicate values are assumed to be equal and the first is taken as the average.

**Value**

A data object of the same class as x with a column for each unique value of ID.

**Author(s)**

Gordon Smyth

**See Also**

[avereps](#).

[02.Classes](#) gives an overview of data classes used in LIMMA.

**Examples**

```
x <- matrix(rnorm(8*3),8,3)
colnames(x) <- c("a","a","b")
avearrays(x)
```

---

avedups

*Average Over Duplicate Spots*

---

**Description**

Condense a microarray data object so that values for within-array replicate spots are replaced with their average.

**Usage**

```
## Default S3 method:
avedups(x, ndups=2, spacing=1, weights=NULL)
## S3 method for class 'MAList'
avedups(x, ndups=x$printer$ndups, spacing=x$printer$spacing, weights=x$weights)
## S3 method for class 'EList'
avedups(x, ndups=x$printer$ndups, spacing=x$printer$spacing, weights=x$weights)
```

**Arguments**

x	a matrix-like object, usually a matrix, MAList or EList object.
ndups	number of within-array replicates for each probe.
spacing	number of spots to step from a probe to its duplicate.
weights	numeric matrix of spot weights.

**Details**

A new data object is computed in which each probe is represented by the (weighted) average of its duplicate spots. For an MAList object, the components M and A are both averaged in this way. For an EList object, the component E is averaged in this way.

If x is of mode "character", then the duplicate values are assumed to be equal and the first is taken as the average.

**Value**

A data object of the same class as x with 1/ndups as many rows.

**Author(s)**

Gordon Smyth

**See Also**

[avereps](#).

[02.Classes](#) gives an overview of data classes used in LIMMA.

---

avereps

*Average Over Irregular Replicate Probes*

---

**Description**

Condense a microarray data object so that values for within-array replicate probes are replaced with their average.

**Usage**

```
## Default S3 method:
avereps(x, ID=rownames(x), ...)
## S3 method for class 'MAList'
avereps(x, ID=NULL, ...)
## S3 method for class 'EList'
avereps(x, ID=NULL, ...)
```

**Arguments**

x	a matrix-like object, usually a matrix, MAList or EList object.
ID	probe identifier.
...	other arguments are not currently used.

## Arguments

RG	a numeric matrix, <a href="#">EListRaw</a> or <a href="#">RGList</a> object.
E	numeric matrix containing foreground intensities.
Eb	numeric matrix containing background intensities.
method	character string specifying correction method. Possible values are "auto", "none", "subtract", "half", "minimum", "movingmin", "edwards" or "normexp". If RG is a matrix, possible values are restricted to "none" or "normexp". The default "auto" is interpreted as "subtract" if background intensities are available or "normexp" if they are not.
offset	numeric value to add to intensities
printer	a list containing printer layout information, see <a href="#">PrintLayout-class</a> . Ignored if RG is a matrix.
normexp.method	character string specifying parameter estimation strategy used by normexp, ignored for other methods. Possible values are "saddle", "mle", "rma" or "rma75".
verbose	logical. If TRUE, progress messages are sent to standard output

## Details

This function implements the background correction methods reviewed or developed in Ritchie et al (2007) and Silver et al (2009). Ritchie et al (2007) recommend `method="normexp"` whenever RG contains local background estimates. Silver et al (2009) shows that either `normexp.method="mle"` or `normexp.method="saddle"` are excellent options for normexp. If RG contains morphological background estimates instead (available from SPOT or GenePix image analysis software), then `method="subtract"` performs well.

If `method="none"` then no correction is done, i.e., the background intensities are treated as zero. If `method="subtract"` then the background intensities are subtracted from the foreground intensities. This is the traditional background correction method, but is not necessarily recommended. If `method="movingmin"` then the background estimates are replaced with the minimums of the backgrounds of the spot and its eight neighbors, i.e., the background is replaced by a moving minimum of 3x3 grids of spots.

The remaining methods are all designed to produce positive corrected intensities. If `method="half"` then any intensity which is less than 0.5 after background subtraction is reset to be equal to 0.5. If `method="minimum"` then any intensity which is zero or negative after background subtraction is set equal to half the minimum of the positive corrected intensities for that array. If `method="edwards"` a log-linear interpolation method is used to adjust lower intensities as in Edwards (2003). If `method="normexp"` a convolution of normal and exponential distributions is fitted to the foreground intensities using the background intensities as a covariate, and the expected signal given the observed foreground becomes the corrected intensity. This results in a smooth monotonic transformation of the background subtracted intensities such that all the corrected intensities are positive.

The normexp method is available in a number of variants depending on how the model parameters are estimated, and these are selected by `normexp.method`. Here "saddle" gives the saddle-point approximation to maximum likelihood from Ritchie et al (2007) and improved by Silver et al (2009), "mle" gives exact maximum likelihood from Silver et al (2009), "rma" gives the background correction algorithm from the RMA-algorithm for Affymetrix microarray data as implemented in the affy package, and "rma75" gives the RMA-75 method from McGee and Chen (2006). In practice "mle" performs well and is nearly as fast as "saddle", but "saddle" is the default for backward compatibility. See [normexp.fit](#) for more details.

The `offset` can be used to add a constant to the intensities before log-transforming, so that the log-ratios are shrunk towards zero at the lower intensities. This may eliminate or reverse the usual 'fanning' of log-ratios at low intensities associated with local background subtraction.

Background correction (background subtraction) is also performed by the `normalizeWithinArrays` method for `RGList` objects, so it is not necessary to call `backgroundCorrect` directly unless one wants to use a method other than simple subtraction. Calling `backgroundCorrect` before `normalizeWithinArrays` will over-ride the default background correction.

### Value

A matrix, `EListRaw` or `RGList` object in which foreground intensities have been background corrected and any components containing background intensities have been removed.

### Author(s)

Gordon Smyth

---

barcodeplot

*Barcode Enrichment Plot*

---

### Description

Display the enrichment of one or two gene sets in a ranked gene list.

**Usage**

```
barcodeplot(statistics, index = NULL, index2 = NULL, gene.weights = NULL,
            weights.label = "Weight", labels = c("Down", "Up"),
            quantiles = c(-1,1)*sqrt(2), col.bars = NULL, alpha = 0.4,
            worm = TRUE, span.worm = 0.45, xlab = "Statistic", ...)
```

**Arguments**

<code>statistics</code>	numeric vector giving the values of statistics to rank genes by.
<code>index</code>	index vector for the gene set. This can be a vector of indices, or a logical vector of the same length as <code>statistics</code> or, in general, any vector such that <code>statistic[index]</code> gives a subset of the statistic values. Can be omitted if <code>gene.weights</code> has same length as <code>statistics</code> , in which case positive values of <code>gene.weights</code> indicate to members of the positive set and negative weights correspond to members of the negative set.
<code>index2</code>	optional index vector for a second (negative) gene set. If specified, then <code>index</code> and <code>index2</code> specify positive and negative genes respectively. Usually used to distinguish down-regulated genes from up-regulated genes.
<code>gene.weights</code>	numeric vector giving directional weights for the genes in the (first) set. Positive and negative weights correspond to positive and negative genes. Ignored if <code>index2</code> is non-null.
<code>weights.label</code>	label describing the entries in <code>gene.weights</code> .
<code>labels</code>	character vector of labels for low and high statistics. First label is associated with low statistics or negative statistics and is displayed at the left end of the plot. Second label is associated with high or positive statistics and is displayed at the right end of the plot.
<code>quantiles</code>	numeric vector of length 2, giving cutoff values for <code>statistics</code> considered small or large respectively. Used to color the rectangle of the barcodeplot.
<code>col.bars</code>	character vector of colors for the vertical bars of the barcodeplot showing the ranks of the gene set members. Defaults to "black" for one set or <code>c("red", "blue")</code> for two sets.
<code>alpha</code>	transparency for vertical bars. When <code>gene.weights</code> are not NULL, values $0 < \alpha < 1$ give semitransparent colors for the vertical bars inside the rectangle. This helps distinguish position bars from the weighted bars and also helps to show the density of the bars when there are many bars. Ignored if <code>gene.weights=NULL</code> .
<code>worm</code>	logical, should enrichment worms be plotted?
<code>span.worm</code>	loess span for enrichment worms. Larger spans give smoother worms.
<code>xlab</code>	x-axis label for statistics.
<code>...</code>	other arguments are passed to plot.

**Details**

This function plots the positions of one or two gene sets in a ranked list of statistics. If there are two sets, then one is considered to be the positive set and the other the down set. For example, the first set and second sets often correspond to genes that are expected to be up- or down-regulated respectively. The function can optionally display varying weights for different genes, for example log-fold-changes from a previous experiment.

The statistics are ranked left to right from smallest to largest. The ranked statistics are represented by a shaded bar or bed, and the positions of the specified subsets are marked by vertical bars,

forming a pattern like a barcode. An enrichment worm optionally shows the relative enrichment of the vertical bars in each part of the plot. The worm is computed by the `tricubeMovingAverage` function.

Barcode plots are often used in conjunction with gene set tests, and show the enrichment of gene sets amongst high or low ranked genes. They were inspired by the set location plot of Subramanian et al (2005), with a number of enhancements, especially the ability to plot positive and negative sets simultaneously. Barcode plots first appeared in the literature in Lim et al (2009). More recent examples can be seen in Liu et al (2014), Sheikh et al (2015), Witkowski et al (2015) and Ng et al (2015).

The function can be used with any of four different calling sequences:

- `index` is specified, but not `index2` or `gene.weights`. Single direction plot.
- `index` and `index2` are specified. Two directional plot.
- `index` and `gene.weights` are specified. `gene.weights` must have same length as `statistics[index]`. Plot will be two-directional if `gene.weights` contains positive and negative values.
- `gene.weights` is specified by not `index` or `index2`. `gene.weights` must have same length as `statistics`. Plot will be two-directional if `gene.weights` contains positive and negative values.

### Value

No value is returned but a plot is produced as a side effect.

```

---

beadCountWeights

*Bead Count Weights for Illumina BeadChips*

---

### Description

Estimates weights which account for biological variation and technical variation resulting from varying bead numbers.

### Usage

```
beadCountWeights(y, x, design = NULL, bead.stdev = NULL, bead.stderr = NULL,
                 nbeads = NULL, array.cv = TRUE, scale = FALSE)
```

**Arguments**

<code>y</code>	an "EList" object or a numeric matrix containing normalized log <sub>2</sub> -expression values.
<code>x</code>	an "EListRaw" object or a numeric matrix of raw expression values, with same dimensions as <code>y</code> .
<code>design</code>	the design matrix of the microarray experiment, with rows corresponding to arrays and columns to coefficients to be estimated. Defaults to <code>y\$design</code> or, if that is NULL, then to a column of ones meaning that the arrays are treated as replicates.
<code>bead.stdev</code>	numeric matrix of bead-level standard deviations.
<code>bead.stderr</code>	numeric matrix of bead-level standard errors. Not required if <code>bead.stdev</code> is set.
<code>nbeads</code>	numeric matrix containing number of beads.
<code>array.cv</code>	logical, should technical variation for each observation be calculated from a constant or array-specific coefficient of variation? The default is to use array-specific coefficients of variation.
<code>scale</code>	logical, should weights be scaled so that the average weight size is the mean of the inverse technical variance along a probe? By default, weights are scaled so that the average weight size along a probe is 1.

**Details**

This function estimates optimum weights using the bead statistics for each probe for an Illumina expression BeadChip. It can be used with any Illumina expression BeadChip, but is most likely to be useful with HumanHT-12 BeadChips.

Arguments `x` and `y` are both required. `x` contains the raw expression values and `y` contains the corresponding log<sub>2</sub> values for the same probes and the same arrays after background correction and normalization. `x` and `y` be any type of object that can be coerced to a matrix, with rows corresponding to probes and columns to arrays. `x` and `y` must contain the same rows and columns in the same order.

The reliability of the normalized expression value for each probe on each array is measured by estimating its technical and biological variability. The bead number weights are the inverse sum of the technical and biological variances.

The technical variance for each probe on each array is inversely proportional to the number of beads and is estimated using array-specific bead-level coefficients of variation.

Coefficients of variation are calculated using raw expression values.

The biological variance for each probe across the arrays are estimated using a Newton iteration, with the assumption that the total residual deviance for each probe from `lmFit` is inversely proportional to the sum of the technical variance and biological variance.

Only one of `bead.stdev` or `bead.stderr` needs to be set. If `bead.stdev` is not provided, then it will be computed as `bead.stderr * sqrt(nbeads)`.

If arguments `bead.stdev` and `nbeads` are not set explicitly in the call, then they will be extracted from `y$other$BEAD_STDEV` and `y$other$Avg_NBEADS`. An EList object containing these components can be created by `read.idat` or `read.ilmn`, see the example code below.

**Value**

A list object with the following components:

weights            numeric matrix of bead number weights  
 cv.constant        numeric value of constant bead-level coefficient of variation  
 cv.array            numeric vector of array-specific bead-level coefficient of variation  
 var.technical     numeric matrix of technical variances  
 var.biological    numeric vector of biological variances

blockDiag

*Block Diagonal Matrix*

---

**Description**

Form a block diagonal matrix from the given blocks.

**Usage**

```
blockDiag(...)
```

**Arguments**

...                numeric matrices

**Details**

This function is sometimes useful for constructing a design matrix for a disconnected two-color microarray experiment in conjunction with `modelMatrix`.

**Value**

A block diagonal matrix with dimensions equal to the sum of the input dimensions

**Author(s)**

Gordon Smyth

**See Also**

bwss

*Between and within sums of squares*

---

**Description**

Sums of squares between and within groups. Allows for missing values.

**Usage**

```
bwss(x, group)
```

**Arguments**

x	a numeric vector giving the responses.
group	a vector or factor giving the grouping variable.

**Details**

This is equivalent to one-way analysis of variance.

**Value**

A list with components

bss	sums of squares between the group means.
wss	sums of squares within the groups.
bdf	degrees of freedom corresponding to bss.
wdf	degrees of freedom corresponding to wss.

**Author(s)**

Gordon Smyth

---

<code>bwss.matrix</code>	<i>Between and within sums of squares for matrix</i>
--------------------------	--

---

### Description

Sums of squares between and within the columns of a matrix. Allows for missing values. This function is called by the [anova](#) method for `MAList` objects.

### Usage

```
bwss.matrix(x)
```

### Arguments

`x` a numeric matrix.

### Details

This is equivalent to a one-way analysis of variance where the columns of the matrix are the groups. If `x` is a matrix then `bwss.matrix(x)` is the same as `bwss(x, col(x))` except for speed of execution.

### Value

A list with components

<code>bss</code>	sums of squares between the column means.
<code>wss</code>	sums of squares within the column means.
<code>bdf</code>	degrees of freedom corresponding to <code>bss</code> .
<code>wdf</code>	degrees of freedom corresponding to <code>wss</code> .

<code>camera</code>	<i>Competitive Gene Set Test Accounting for Inter-gene Correlation</i>
---------------------	--

---

### Description

Test whether a set of genes is highly ranked relative to other genes in terms of differential expression, accounting for inter-gene correlation.

## Usage

```
## Default S3 method:
camera(y, index, design, contrast = ncol(design), weights = NULL,
       use.ranks = FALSE, allow.neg.cor=FALSE, inter.gene.cor=0.01, trend.var = FALSE,
       sort = TRUE, ...)
## Default S3 method:
cameraPR(statistic, index, use.ranks = FALSE, inter.gene.cor=0.01, sort = TRUE, ...)
interGeneCorrelation(y, design)
```

## Arguments

<code>y</code>	a numeric matrix of log-expression values or log-ratios of expression values, or any data object containing such a matrix. Rows correspond to probes and columns to samples. Any type of object that can be processed by <a href="#">getEAWP</a> is acceptable.
<code>statistic</code>	a numeric vector of genewise statistics. If <code>index</code> contains gene IDs, then <code>statistic</code> should be a named vector with the gene IDs as names.
<code>index</code>	an index vector or a list of index vectors. Can be any vector such that <code>y[index, ]</code> of <code>statistic[index]</code> selects the rows corresponding to the test set. The list can be made using <a href="#">ids2indices</a> .
<code>design</code>	design matrix.
<code>contrast</code>	contrast of the linear model coefficients for which the test is required. Can be an integer specifying a column of <code>design</code> , or else a numeric vector of same length as the number of columns of <code>design</code> .
<code>weights</code>	numeric matrix of precision weights. Can be a matrix of the same size as <code>y</code> , or a numeric vector of array weights with length equal to <code>ncol(y)</code> , or a numeric vector of gene weights with length equal to <code>nrow(y)</code> .
<code>use.ranks</code>	do a rank-based test (TRUE) or a parametric test (FALSE)?
<code>allow.neg.cor</code>	should reduced variance inflation factors be allowed for negative correlations?
<code>inter.gene.cor</code>	numeric, optional preset value for the inter-gene correlation within tested sets. If NA or NULL, then an inter-gene correlation will be estimated for each tested set.
<code>trend.var</code>	logical, should an empirical Bayes trend be estimated? See <a href="#">eBayes</a> for details.
<code>sort</code>	logical, should the results be sorted by p-value?
<code>...</code>	other arguments are not currently used

## Details

`camera` and `interGeneCorrelation` implement methods proposed by Wu and Smyth (2012). `camera` performs a *competitive* test in the sense defined by Goeman and Buhlmann (2007). It tests whether the genes in the set are highly ranked in terms of differential expression relative to genes not in the set. It has similar aims to `geneSetTest` but accounts for inter-gene correlation. See [roast](#) for an analogous *self-contained* gene set test.

The function can be used for any microarray experiment which can be represented by a linear model. The design matrix for the experiment is specified as for the `lmFit` function, and the contrast of interest is specified as for the `contrasts.fit` function. This allows users to focus on differential expression for any coefficient or contrast in a linear model by giving the vector of test statistic values.

camera estimates p-values after adjusting the variance of test statistics by an estimated variance inflation factor. The inflation factor depends on estimated genewise correlation and the number of genes in the gene set.

By default, camera uses `interGeneCorrelation` to estimate the mean pair-wise correlation within each set of genes. camera can alternatively be used with a preset correlation specified by `inter.gene.cor` that is shared by all sets. This usually works best with a small value, say `inter.gene.cor=0.01`.

If `interGeneCorrelation=NA`, then camera will estimate the inter-gene correlation for each set. In this mode, camera gives rigorous error rate control for all sample sizes and all gene sets. However, in this mode, highly co-regulated gene sets that are biological interpretable may not always be ranked at the top of the list.

With `interGeneCorrelation=0.01`, camera will rank biologically interpretable sets more highly. This gives a useful compromise between strict error rate control and interpretable gene set rankings.

cameraPR is a "pre-ranked" version of camera where the genes are pre-ranked according to a pre-computed statistic.

### Value

camera and cameraPR return a data.frame with a row for each set and the following columns:

NGenes	number of genes in set.
Correlation	inter-gene correlation (only included if the <code>inter.gene.cor</code> was not preset).
Direction	direction of change ("Up" or "Down").
PValue	two-tailed p-value.
FDR	Benjamini and Hochberg FDR adjusted p-value.

`interGeneCorrelation` returns a list with components:

vif	variance inflation factor.
correlation	inter-gene correlation.

### Note

The default settings for `inter.gene.cor` and `allow.neg.cor` were changed to the current values in limma 3.29.6. Previously, the default was to estimate an inter-gene correlation for each set. To reproduce the earlier default, use `allow.neg.cor=TRUE` and `inter.gene.cor=NA`.

cbind

*Combine RGList, MAList, EList or EListRaw Objects***Description**

Combine a set of RGList, MAList, EList or EListRaw objects.

**Usage**

```

## S3 method for class 'RGList'
cbind(..., deparse.level=1)
## S3 method for class 'RGList'
rbind(..., deparse.level=1)

```

**Arguments**

... RGList, MAList, EList or EListRaw objects.

deparse.level not currently used, see [cbind](#) in the base package

**Details**

`cbind` combines data objects assuming the same probes in the same order but different arrays. `rbind` combines data objects assuming equivalent arrays, i.e., the same RNA targets, but different probes.

For `cbind`, the matrices of expression data from the individual objects are cbinded. The data.frames of target information, if they exist, are rbinded. The combined data object will preserve any additional components or attributes found in the first object to be combined. For `rbind`, the matrices of expression data are rbinded while the target information, in any, is unchanged.

**Value**

An [RGList](#), [MAList](#), [EList](#) or [EListRaw](#) object holding data from all the arrays and all genes from the individual objects.

classifyTests

*Multiple Testing Genewise Across Contrasts*

---

**Description**

For each gene, classify a series of related t-statistics as up, down or not significant.

**Usage**

```
classifyTestsF(object, cor.matrix=NULL, df=Inf, p.value=0.01, fstat.only=FALSE)
classifyTestsT(object, t1=4, t2=3)
classifyTestsP(object, df=Inf, p.value=0.05, method="holm")
FStat(object, cor.matrix=NULL)
```

**Arguments**

object	numeric matrix of t-statistics or an MArrayLM object from which the t-statistics may be extracted.
cor.matrix	covariance matrix of each row of t-statistics. Defaults to the identity matrix.
df	numeric vector giving the degrees of freedom for the t-statistics. May have length 1 or length equal to the number of rows of tstat.
p.value	numeric value between 0 and 1 giving the desired size of the test
fstat.only	logical, if TRUE then return the overall F-statistic as for FStat instead of classifying the test results
t1	first critical value for absolute t-statistics
t2	second critical value for absolute t-statistics
method	character string specifying p-value adjustment method. See <a href="#">p.adjust</a> for possible values.

## Details

Note that these functions do not adjust for multiple testing across genes. The adjustment for multiple testing is across the contrasts rather than the more usual control across genes. The functions described here are called by `decideTests`. Most users should use `decideTests` rather than using these functions directly.

These functions implement multiple testing procedures for determining whether each statistic in a matrix of t-statistics should be considered significantly different from zero. Rows of `tstat` correspond to genes and columns to coefficients or contrasts.

`FStat` computes the gene-wise F-statistics for testing all the contrasts equal to zero. It is equivalent to `classifyTestsF` with `fstat.only=TRUE`.

`classifyTestsF` uses a nested F-test approach giving particular attention to correctly classifying genes which have two or more significant t-statistics, i.e., are differential expressed under two or more conditions. For each row of `tstat`, the overall F-statistic is constructed from the t-statistics as for `FStat`. At least one contrast will be classified as significant if and only if the overall F-statistic is significant. If the overall F-statistic is significant, then the function makes a best choice as to which t-statistics contributed to this result. The methodology is based on the principle that any t-statistic should be called significant if the F-test is still significant for that row when all the larger t-statistics are set to the same absolute size as the t-statistic in question.

`classifyTestsT` and `classifyTestsP` implement simpler classification schemes based on threshold or critical values for the individual t-statistics in the case of `classifyTestsT` or p-values obtained from the t-statistics in the case of `classifyTestsP`. For `classifyTestsT`, classifies any t-statistic with absolute greater than `t2` as significant provided that at least one t-statistic for that gene is at least `t1` in absolute value. `classifyTestsP` applied p-value adjustment from `p.adjust` to the p-values for each gene.

If `tstat` is an `MArrayLM` object, then all arguments except for `p.value` are extracted from it.

`cor.matrix` is the same as the correlation matrix of the coefficients from which the t-statistics are calculated. If `cor.matrix` is not specified, then it is calculated from `design` and `contrasts` if at least `design` is specified or else defaults to the identity matrix. In terms of `design` and `contrasts`, `cor.matrix` is obtained by standardizing the matrix

```
t(contrasts) %*% solve(t(design) %*% design) %*% contrasts
```

to a correlation matrix.

## Value

An object of class `TestResults`. This is essentially a numeric matrix with elements `-1`, `0` or `1` depending on whether each t-statistic is classified as significantly negative, not significant or significantly positive respectively.

`FStat` produces a numeric vector of F-statistics with attributes `df1` and `df2` giving the corresponding degrees of freedom.

---

 contrastAsCoef

---

*Reform a Design Matrix so that Contrasts Become Coefficients*

---

**Description**

Reform a design matrix so that one or more coefficients from the new matrix correspond to specified contrasts of coefficients from the old matrix.

**Usage**

```
contrastAsCoef(design, contrast=NULL, first=TRUE)
```

**Arguments**

design	numeric design matrix.
contrast	numeric matrix with rows corresponding to columns of the design matrix (coefficients) and columns containing contrasts. May be a vector if there is only one contrast.
first	logical, should coefficients corresponding to contrasts be the first columns (TRUE) or last columns (FALSE) of the output design matrix.

**Details**

If the contrasts contained in the columns of `contrast` are not linearly dependent, then superfluous columns are dropped until the remaining matrix has full column rank. The number of retained contrasts is stored in `qr$rank` and the retained columns are given by `qr$pivot`.

**Value**

A list with components

design	reformed design matrix
coef	columns of design matrix which hold the meaningful coefficients
qr	QR-decomposition of contrast matrix

**Author(s)**

Gordon Smyth

coef(fit1)
coef(fit1)
coef(fit2)

```

---

contrasts.fit

---

*Compute Contrasts from Linear Model Fit*

---

**Description**

Given a linear model fit to microarray data, compute estimated coefficients and standard errors for a given set of contrasts.

**Usage**

```
contrasts.fit(fit, contrasts=NULL, coefficients=NULL)
```

**Arguments**

fit	an <a href="#">MArrayLM</a> object or a list object produced by the function <code>lm.series</code> or equivalent. Must contain components <code>coefficients</code> and <code>stdev.unscaled</code> .
contrasts	numeric matrix with rows corresponding to coefficients in <code>fit</code> and columns containing contrasts. May be a vector if there is only one contrast.
coefficients	vector indicating which coefficients are to be kept in the revised fit object. An alternative way to specify the contrasts.

**Details**

This function accepts input from any of the functions `lmFit`, `lm.series`, `mrlm`, `gls.series` or `lmScFit`. The function re-orientates the fitted model object from the coefficients of the original design matrix to any set of contrasts of the original coefficients. The coefficients, unscaled standard deviations and correlation matrix are re-calculated in terms of the contrasts.

The idea of this function is to fit a full-rank model using `lmFit` or equivalent, then use `contrasts.fit` to obtain coefficients and standard errors for any number of contrasts of the coefficients of the original model. Unlike the design matrix input to `lmFit`, which normally has one column for each treatment in the experiment, the matrix `contrasts` may have any number of columns and these are not required to be linearly independent. Methods of assessing differential expression, such as `eBayes` or `classifyTestsF`, can then be applied to fitted model object.

The `coefficients` argument provides a simpler way to specify the contrasts matrix when the desired contrasts are just a subset of the original coefficients.

**Value**

An list object of the same class as `fit`, usually `MArrayLM`. This is a list with components

<code>coefficients</code>	numeric matrix containing the estimated coefficients for each contrast for each probe.
<code>stdev.unscaled</code>	numeric matrix conformal with <code>coef</code> containing the unscaled standard deviations for the coefficient estimators.
<code>cov.coefficients</code>	numeric matrix giving the unscaled covariance matrix of the estimable coefficients.
<code>...</code>	any other components found in <code>fit</code> are passed through unchanged.

**Note**

For efficiency reasons, this function does not re-factorize the design matrix for each probe. A consequence is that, if the design matrix is non-orthogonal and the original fit included precision weights or missing values, then the unscaled standard deviations produced by this function are approximate rather than exact. The approximation is usually acceptable. If not, then the issue can be avoided by redefining the design matrix to fit the contrasts directly.

Even with precision weights, the results from `contrasts.fit` are always exact if the coefficients being compared are statistically independent. This will always be true, for example, if the original fit was a oneway model and the group-means (no-intercept) parametrization was used for the design matrix.

```
# Simulate gene expression data: 6 microarrays and 100 genes
# with one gene differentially expressed in first 3 arrays
M <- matrix(rnorm(100*6, sd=0.3), 100, 6)
M[1,1:3] <- M[1,1:3] + 2
# Design matrix corresponds to oneway layout, columns are orthogonal
design <- cbind(First3Arrays=c(1,1,1,0,0,0), Last3Arrays=c(0,0,0,1,1,1))
fit <- lmFit(M, design=design)
# Would like to consider original two estimates plus difference between first 3 and last 3 arrays
contrast.matrix <- cbind(First3=c(1,0), Last3=c(0,1), "Last3-First3"=c(-1,1))
fit2 <- contrasts.fit(fit, contrast.matrix)
fit2 <- eBayes(fit2)
# Large values of eb$t indicate differential expression
results <- classifyTestsF(fit2)
vennCounts(results)
```

---

controlStatus	<i>Set Status of each Spot from List of Spot Types</i>
---------------	--

---

**Description**

Determine the type (or status) of each spot in the gene list.

**Usage**

```
controlStatus(types, genes, spottypecol="SpotType", regexpcol, verbose=TRUE)
```

**Arguments**

types	dataframe containing spot type specifiers, usually input using readSpotTypes.
genes	dataframe containing gene annotation, or an object of class RGList, MAList, EListRaw, EList or MArrayLM from which the gene annotation can be extracted.
spottypecol	integer or name specifying column of types containing spot type names.
regexpcol	vector of integers or column names specifying columns of types containing regular expressions. Defaults to any column names in common between types and genes.
verbose	logical, if TRUE then progress on pattern matching is reported to the standard output channel.

**Details**

This function constructs a vector of status codes by searching for patterns in the gene list. The data frame genes contains gene IDs and should have as many rows as there are spots on the microarrays. Such a data frame is often read using readGAL. The data frame types has as many rows as you want to distinguish types of spots in the gene list. This data frame should contain a column or columns, the regexpcol columns, which have the same names as columns in genes and which contain patterns to match in the gene list. Another column, the spottypecol, contains the names of the spot types. Any other columns are assumed to contain plotting parameters, such as colors or symbols, to be associated with the spot types.

The patterns in the regexpcol columns are simplified regular expressions. For example, AA\* means any string starting with AA, \*AA means any code ending with AA, AA means exactly these two letters, \*AA\* means any string containing AA, AA. means AA followed by exactly one other character and AA\. means exactly AA followed by a period and no other characters. Any other regular expressions are allowed but the codes ^ for beginning of string and \$ for end of string should not be included.

Note that the patterns are matched sequentially from first to last, so more general patterns should be included first. For example, it is often a good idea to include a default spot-type as the first line in types with pattern \* for all regexpcol columns and default plotting parameters.

**Value**

Character vector specifying the type (or status) of each spot on the array. Attributes contain plotting parameters associated with each spot type.

**Examples**

```
genes <- data.frame(
  ID=c("Control", "Control", "Control", "Control", "AA1", "AA2", "AA3", "AA4"),
  Name=c("Ratio 1", "Ratio 2", "House keeping 1", "House keeping 2",
         "Gene 1", "Gene 2", "Gene 3", "Gene 4"))
types <- data.frame(
  SpotType=c("Gene", "Ratio", "Housekeeping"),
  ID=c("*", "Control", "Control"),
  Name=c("*", "Ratio*", "House keeping*"),
  col=c("black", "red", "blue"))
status <- controlStatus(types, genes)
```

---

 coolmap

*Heatmap of gene expression values*

---

**Description**

Create a heatmap of a matrix of log-expression values.

**Usage**

```
coolmap(x, cluster.by="de pattern", col=NULL,
        linkage.row="complete", linkage.col="complete", show.dendrogram="both", ...)
```

**Arguments**

x	any data object that can be coerced to a matrix of log-expression values, for example an ExpressionSet or EList. Rows represent genes and columns represent RNA samples.
cluster.by	choices are "de pattern" or "expression level". In the former case, the intention is to cluster by relative changes in expression, so genes are clustered by Pearson correlation and log-expression values are mean-corrected by rows for the plot. In the latter case, the intention is to cluster by absolute expression, so genes are clustered by Euclidean and log-expression values are not mean-corrected.
col	character vector specifying the color panel. Can be either the name of the panel or a vector of R colors that can be passed directly to the heatmap.2 function. Possible panel names are "redblue", "redgreen", "yellowblue" or "whitered". Defaults to "redblue" if cluster.by="de pattern" or "yellowblue" if cluster.by="expression level".
linkage.row	linkage criterion used to cluster the rows. Choices are "none", "ward", "ward.D", "ward.D2", "single", "complete", "average", "mcquitty", "median" or "centroid", with "ward" treated as "ward.D2".
linkage.col	linkage criterion used to cluster the columns. Choices are the same as for linkage.row.
show.dendrogram	choices are "row", "column", "both" or "none".
...	any other arguments are passed to heatmap.2.

**Details**

This function calls the `heatmap.2` function in the `ggplots` package with sensible argument settings for genomic log-expression data. The default settings for `heatmap.2` are often not ideal for expression data, and overriding the defaults requires explicit calls to `hclust` and `as.dendrogram` as well as prior standardization of the data values. The `coolmap` function implements our preferred defaults for the two most common types of heatmaps. When clustering by relative expression (`cluster.by="de pattern"`), it implements a row standardization that takes account of NA values and standard deviations that might be zero.

**Value**

A plot is created on the current graphics device. A list is also invisibly returned, see [heatmap.2](#) for details.

**Author(s)**

Gordon Smyth

**Examples**

```
# Simulate gene expression data for 50 genes and 6 microarrays.
# Samples are in two groups
# First 50 probes are differentially expressed in second group
ngenes <- 50
sd <- 0.3*sqrt(4/rchisq(ngenes,df=4))
x <- matrix(rnorm(ngenes*6,sd=sd),ngenes,6)
rownames(x) <- paste("Gene",1:ngenes)
x <- x + seq(from=0, to=16, length=ngenes)
x[,4:6] <- x[,4:6] + 2
coolmap(x)
```

---

cumOverlap

*Cumulative Overlap Analysis of Ordered Lists*

---

**Description**

Test whether the leading members of ordered lists significantly overlap.

**Usage**

```
cumOverlap(o11, o12)
```

**Arguments**

`o11` vector containing first ordered list. Duplicate values not allowed.

`o12` vector containing second ordered list. Should contain the same values as found in `o11` but in a possibly different order. Duplicate values not allowed.

## Details

The function compares the top  $n$  members of each list, for every possible  $n$ , and conducts an hypergeometric test for overlap. The function returns the value of  $n$  giving the smallest p-value.

The p-values are adjusted for multiple testing in a similar way to Bonferroni's method, but starting from the top of the ranked list instead of from the smallest p-values. This approach is designed to be sensitive to contexts where the number of IDs involved in the significant overlap are a small proportion of the total.

The vectors `o11` and `o12` do not need to be of the same length, but only values in common between the two vectors will be used in the calculation.

This method was described in Chapter 4 of Wu (2011).

## Value

List containing the following components:

<code>n.total</code>	integer, total number of values in common between <code>o11</code> and <code>o12</code> .
<code>n.min</code>	integer, top table length leading to smallest adjusted p-value.
<code>p.min</code>	smallest adjusted p-value.
<code>n.overlap</code>	integer, number of overlapping IDs in first <code>n.min</code> .
<code>id.overlap</code>	vector giving the overlapping IDs in first <code>n.min</code> .
<code>p.value</code>	numeric, vector of p-values for each possible top table length.
<code>adj.p.value</code>	numeric, vector of Bonferroni adjusted p-values for each possible top table length.

coa$p.min
coa$id.overlap
```

decideTests

*Multiple Testing Across Genes and Contrasts***Description**

Identify which genes are significantly differentially expressed for each contrast from a fit object containing p-values and test statistics. A number of different multiple testing strategies are offered that adjust for multiple testing down the genes as well as across contrasts for each gene.

**Usage**

```
## S3 method for class 'MArrayLM'
decideTests(object, method = "separate", adjust.method = "BH", p.value = 0.05,
            lfc = 0, ...)
## Default S3 method:
decideTests(object, method = "separate", adjust.method = "BH", p.value = 0.05,
            lfc = 0, coefficients = NULL, cor.matrix = NULL, tstat = NULL, df = Inf,
            genewise.p.value = NULL, ...)
```

**Arguments**

object	a numeric matrix of p-values or an MArrayLM object from which p-values and t-statistics can be extracted.
method	character string specifying how genes and contrasts are to be combined in the multiple testing scheme. Choices are "separate", "global", "hierarchical" or "nestedF".
adjust.method	character string specifying p-value adjustment method. Possible values are "none", "BH", "fdr" (equivalent to "BH"), "BY" and "holm". See <a href="#">p.adjust</a> for details.
p.value	numeric value between 0 and 1 giving the required family-wise error rate or false discovery rate.
lfc	numeric, minimum absolute log2-fold-change required.
coefficients	numeric matrix of coefficients or log2-fold-changes. Of same dimensions as object.
cor.matrix	correlation matrix of coefficients. Square matrix of dimension ncol(object).
tstat	numeric matrix of t-statistics. Of same dimensions as object.
df	numeric vector of length nrow(object) giving degrees of freedom for the t-statistics.
genewise.p.value	numeric vector of length nrow(object) containing summary gene-level p-values for use with method="hierarchical".
...	other arguments are not used.

**Details**

This function can be applied to a matrix of p-values but is more often applied to an MArrayLM fit object produced by eBayes or treat. In either case, rows of object correspond to genes and columns to coefficients or contrasts.

This function applies a multiple testing procedure and a significance level cutoff to the statistics contained in object. It implements a number of multiple testing procedures for determining whether each statistic should be considered significantly different from zero.

The setting `method="separate"` is equivalent to using `topTable` separately for each coefficient in the linear model fit, and will identify the same probes as significantly differentially expressed if `adjust.method` is the same. `method="global"` will treat the entire matrix of t-statistics as a single vector of unrelated tests. `method="hierarchical"` adjusts down genes and then across contrasts. `method="nestedF"` adjusts down genes and then uses `classifyTestsF` to classify contrasts as significant or not for the selected genes. Please see the *limma User's Guide* for a discussion of the statistical properties of these methods.

### Value

An object of class `TestResults`. This is essentially a numeric matrix with elements  $-1$ ,  $0$  or  $1$  depending on whether each t-statistic is classified as significantly negative, not significant or significantly positive.

If `lfc > 0` then contrasts are judged significant only when the log<sub>2</sub>-fold change is at least this large in absolute value. For example, one might choose `lfc=log2(1.5)` to restrict to 50% changes or `lfc=1` for 2-fold changes. In this case, contrasts must satisfy both the p-value and the fold-change cutoff to be judged significant.

### Note

Although this function enables users to set p-value and lfc cutoffs simultaneously, this combination criterion is not generally recommended. Unless the fold changes and p-values are very highly correlated, the addition of a fold change cutoff can increase the family-wise error rate or false discovery rate above the nominal level. Users wanting to use fold change thresholding are recommended to use `treat` instead of `eBayes` and to leave `lfc` at the default value when using `decideTests`.

### Author(s)

Gordon Smyth

---

designI2M

*Convert Individual Channel Design Matrix to M-A Format*

---

### Description

Convert a design matrix in terms of individual channels to ones in terms of M-values or A-values for two-color microarray data.

### Usage

```
designI2M(design)
designI2A(design)
```

**Arguments**

`design` numeric model matrix with one row for each channel observation, i.e., twice as many rows as arrays

**Details**

If `design` is a model matrix suitable for modelling individual log-intensities for two color microarray data, then `designI2M` computes the corresponding model matrix for modelling M-values (log-ratios) and `designI2A` computes the model matrix for modelling A-values (average log-intensities).

Note that the matrices `designI2M(design)` or `designI2A(design)` may be singular if not all of the coefficients are estimable from the M or A-values. In that case there will be columns containing entirely zeros.

**Value**

numeric model matrix with half as many rows as `design`

**Author(s)**

Gordon Smyth

**See Also**

[model.matrix](#) in the stats package.

An overview of individual channel linear model functions in limma is given by [07.SingleChannel](#).

**Examples**

```
X <- cbind(1,c(1,1,1,1,0,0,0,0),c(0,0,0,0,1,1,1,1))
designI2M(X)
designI2A(X)
```

---

detectionPValues

*Detection P-Values from Negative Controls*

---

**Description**

Compute the proportion of negative controls greater than each observed expression value. Particularly useful for Illumina BeadChips.

**Usage**

```
## S3 method for class 'EListRaw'
detectionPValues(x, status = NULL, ...)
## Default S3 method:
detectionPValues(x, status, negctrl = "negative", ...)
```

**Arguments**

<code>x</code>	object of class <code>EListRaw</code> or a numeric matrix containing raw intensities for regular and control probes from a series of microarrays.
<code>status</code>	character vector giving probe types. Defaults to <code>x\$genes\$Status</code> if <code>x</code> is an <code>EListRaw</code> object.
<code>negctrl</code>	character string identifier for negative control probes.
<code>...</code>	other arguments are not currently used.

**Details**

The rows of `x` for which `status == negctrl` are assumed to correspond to negative control probes.

For each column of `x`, the detection p-values are defined as  $(N.eq/2 + N.gt) / N.neg$ , where `N.gt` is the number of negative controls with expression greater than the observed value, `N.eq` is the number of negative controls with expression equal to the observed value, and `N.neg` is the total number of negative controls.

When used on Illumina BeadChip data, this function produces essentially the same detection p-values as returned by Illumina's GenomeStudio software.

**Value**

numeric matrix of same dimensions as `x` containing detection p-values.

`read.idat` reads Illumina BeadChip expression data from binary IDAT files.

`neqc` performs normexp background correction and quantile normalization aided by control probes.

**Examples**

```
## Not run:  
# Read Illumina binary IDAT files  
x <- read.idat(idat, bgx)  
x$genes$DetectionPValue <- detectionPValues(x)  
y <- neqc(x)  
  
## End(Not run)
```

diffSplice

*Test for Differential Splicing***Description**

Given a linear model fit at the exon level, test for differences in exon retention between experimental conditions.

**Usage**

```
diffSplice(fit, geneid, exonid=NULL, robust=FALSE, verbose=TRUE)
```

**Arguments**

fit	an MArrayLM fitted model object produced by <code>lmFit</code> or <code>contrasts.fit</code> . Rows should correspond to exons.
geneid	gene identifiers. Either a vector of length <code>nrow(fit)</code> or the name of the column of <code>fit\$genes</code> containing the gene identifiers. Rows with the same ID are assumed to belong to the same gene.
exonid	exon identifiers. Either a vector of length <code>nrow(fit)</code> or the name of the column of <code>fit\$genes</code> containing the exon identifiers.
robust	logical, should the estimation of the empirical Bayes prior parameters be robustified against outlier sample variances?
verbose	logical, if TRUE some diagnostic information about the number of genes and exons is output.

**Details**

This function tests for differential exon usage for each gene and for each column of `fit`.

Testing for differential exon usage is equivalent to testing whether the log-fold-changes in the `fit` differ between exons for the same gene. Two different tests are provided. The first is an F-test for differences between the log-fold-changes. The other is a series of t-tests in which each exon is compared to the average of all other exons for the same gene. The exon-level t-tests are converted into a genewise test by adjusting the p-values for the same gene by Simes method. The minimum adjusted p-value is then used for each gene.

This function can be used on data from an exon microarray or can be used in conjunction with `voom` for exon-level RNA-seq counts.

**Value**

An object of class `MArrayLM` containing both exon level and gene level tests. Results are sorted by `geneid` and by `exonid` within gene.

coefficients	numeric matrix of coefficients of same dimensions as <code>fit</code> . Each coefficient is the difference between the log-fold-change for that exon versus the average log-fold-change for all other exons for the same gene.
t	numeric matrix of moderated t-statistics, of same dimensions as <code>fit</code> .
p.value	numeric vector of p-values corresponding to the t-statistics
genes	data.frame of exon annotation

`gene.colname` character string giving the name of the column of genes containing gene IDs  
`gene.F` numeric matrix of moderated F-statistics, one row for each gene.  
`gene.F.p.value` numeric matrix of p-values corresponding to `gene.F`  
`gene.simes.p.value`  
 numeric matrix of Simes adjusted p-values, one row for each gene.  
`gene.genes` data.frame of gene annotation.

plotSplice(ex)

## End(Not run)
```

---

 dim

*Retrieve the Dimensions of an RGList, MAList or MArrayLM Object*

---

**Description**

Retrieve the number of rows (genes) and columns (arrays) for an RGList, MAList or MArrayLM object.

**Usage**

```
## S3 method for class 'RGList'
dim(x)
```

**Arguments**

`x` an object of class RGList, MAList or MArrayLM

**Details**

Microarray data objects share many analogies with ordinary matrices in which the rows correspond to spots or genes and the columns to arrays. These methods allow one to extract the size of microarray data objects in the same way that one would do for ordinary matrices.

A consequence is that row and column commands `nrow(x)`, `ncol(x)` and so on also work.

**Value**

Numeric vector of length 2. The first element is the number of rows (genes) and the second is the number of columns (arrays).

**Author(s)**

Gordon Smyth

**See Also**

[dim](#) in the base package.

[02.Classes](#) gives an overview of data classes used in LIMMA.

**Examples**

```
M <- A <- matrix(11:14,4,2)
rownames(M) <- rownames(A) <- c("a","b","c","d")
colnames(M) <- colnames(A) <- c("A1","A2")
MA <- new("MArrayLM",list(M=M,A=A))
dim(M)
ncol(M)
nrow(M)
```

---

dimnames

*Retrieve the Dimension Names of an RGList, MAList, EList, EListRaw or MArrayLM Object*

---

**Description**

Retrieve the dimension names of a microarray data object.

**Usage**

```
## S3 method for class 'RGList'
dimnames(x)
## S3 replacement method for class 'RGList'
dimnames(x) <- value
```

**Arguments**

**x** an object of class RGList, MAList, EList, EListRaw or (not for assignment) MArrayLM

**value** a possible value for dimnames(x): see [dimnames](#)

**Details**

The dimension names of a microarray object are the same as those of the most important matrix component of that object.

A consequence is that rownames and colnames will work as expected.

**Value**

Either NULL or a list of length 2. If a list, its components are either NULL or a character vector the length of the appropriate dimension of *x*.

**Author(s)**

Gordon Smyth

**See Also**

[dimnames](#) in the base package.

[02.Classes](#) gives an overview of data classes used in LIMMA.

---

 dupcor

---

*Correlation Between Duplicates*

---

**Description**

Estimate the correlation between duplicate spots (regularly spaced replicate spots on the same array) or between technical replicates from a series of arrays.

**Usage**

```
duplicateCorrelation(object, design=NULL, ndups=2, spacing=1, block=NULL,
                    trim=0.15, weights=NULL)
```

**Arguments**

object	a numeric matrix of expression values, or any data object from which <code>as.matrix</code> will extract a suitable matrix such as an <code>MAList</code> , <code>marrayNorm</code> or <code>ExpressionSet</code> object. If object is an <code>MAList</code> object then the arguments <code>design</code> , <code>ndups</code> , <code>spacing</code> and <code>weights</code> will be extracted from it if available and do not have to be specified as arguments. Specifying these arguments explicitly will over-rule any components found in the data object.
design	the design matrix of the microarray experiment, with rows corresponding to arrays and columns to comparisons to be estimated. The number of rows must match the number of columns of object. Defaults to the unit vector meaning that the arrays are treated as replicates.
ndups	a positive integer giving the number of times each gene is printed on an array. <code>nrow(object)</code> must be divisible by <code>ndups</code> . Will be ignored if <code>block</code> is specified.
spacing	the spacing between the rows of object corresponding to duplicate spots, <code>spacing=1</code> for consecutive spots
block	vector or factor specifying a blocking variable
trim	the fraction of observations to be trimmed from each end of <code>tanh(all.correlations)</code> when computing the trimmed mean.
weights	an optional numeric matrix of the same dimension as object containing weights for each spot. If smaller than object then it will be filled out the same size.

## Details

When `block=NULL`, this function estimates the correlation between duplicate spots (regularly spaced within-array replicate spots). If `block` is not null, this function estimates the correlation between repeated observations on the blocking variable. Typically the blocks are biological replicates and the repeated observations are technical replicates. In either case, the correlation is estimated by fitting a mixed linear model by REML individually for each gene. The function also returns a consensus correlation, which is a robust average of the individual correlations, which can be used as input for functions `lmFit` or `glS.series`.

At this time it is not possible to estimate correlations between duplicate spots and between technical replicates simultaneously. If `block` is not null, then the function will set `ndups=1`, which is equivalent to ignoring duplicate spots.

For this function to return statistically useful results, there must be at least two more arrays than the number of coefficients to be estimated, i.e., two more than the column rank of design.

The function may take long time to execute as it fits a mixed linear model for each gene for an iterative algorithm. It is not uncommon for the function to return a small number of warning messages that correlation estimates cannot be computed for some individual genes. This is not a serious concern providing that there are only a few such warnings and the total number of genes is large. The consensus estimator computed by this function will not be materially affected by a small number of genes.

## Value

A list with components

`consensus.correlation`

the average estimated inter-duplicate correlation. The average is the trimmed mean of the individual correlations on the `atanh`-transformed scale.

`cor`

same as `consensus.correlation`, for compatibility with earlier versions of the software

`atanh.correlations`

numeric vector of length `nrow(object)/ndups` giving the individual genewise `atanh`-transformed correlations.

eBayes

*Empirical Bayes Statistics for Differential Expression*

---

**Description**

Given a microarray linear model fit, compute moderated t-statistics, moderated F-statistic, and log-odds of differential expression by empirical Bayes moderation of the standard errors towards a common value.

**Usage**

```

eBayes(fit, proportion = 0.01, stdev.coef.lim = c(0.1,4),
       trend = FALSE, robust = FALSE, winsor.tail.p = c(0.05,0.1))
treat(fit, lfc = log2(1.2), trend = FALSE, robust = FALSE, winsor.tail.p = c(0.05,0.1))

```

**Arguments**

**fit** an MArrayLM fitted model object produced by `lmFit` or `contrasts.fit`. For `ebayes` only, `fit` can alternatively be an unclassed list produced by `lm.series`, `gls.series` or `mrlm` containing components `coefficients`, `stdev.unscaled`, `sigma` and `df.residual`.

<code>proportion</code>	numeric value between 0 and 1, assumed proportion of genes which are differentially expressed
<code>stdev.coef.lim</code>	numeric vector of length 2, assumed lower and upper limits for the standard deviation of log <sub>2</sub> -fold-changes for differentially expressed genes
<code>trend</code>	logical, should an intensity-trend be allowed for the prior variance? Default is that the prior variance is constant.
<code>robust</code>	logical, should the estimation of <code>df.prior</code> and <code>var.prior</code> be robustified against outlier sample variances?
<code>winsor.tail.p</code>	numeric vector of length 1 or 2, giving left and right tail proportions of <code>x</code> to Winsorize. Used only when <code>robust=TRUE</code> .
<code>lfc</code>	the minimum log <sub>2</sub> -fold-change that is considered scientifically meaningful

## Details

These functions are used to rank genes in order of evidence for differential expression. They use an empirical Bayes method to squeeze the genewise-wise residual variances towards a common value (or towards a global trend) (Smyth, 2004; Phipson et al, 2016). The degrees of freedom for the individual variances are increased to reflect the extra information gained from the empirical Bayes moderation, resulting in increased statistical power to detect differential expression.

These functions accept as input an `MArrayLM` fitted model object `fit` produced by `lmFit`. The columns of `fit` define a set of contrasts which are to be tested equal to zero. The fitted model object may have been processed by `contrasts.fit` before being passed to `eBayes` to convert the coefficients of the original design matrix into an arbitrary number of contrasts.

The empirical Bayes moderated t-statistics test each individual contrast equal to zero. For each gene (row), the moderated F-statistic tests whether all the contrasts are zero. The F-statistic is an overall test computed from the set of t-statistics for that probe. This is exactly analogous the relationship between t-tests and F-statistics in conventional anova, except that the residual mean squares have been moderated between genes.

The estimates `s2.prior` and `df.prior` are computed by `fitFDist`. `s2.post` is the weighted average of `s2.prior` and  $\sigma^2$  with weights proportional to `df.prior` and `df.residual` respectively. The log-odds of differential expression `lods` was called the *B-statistic* by Loennstedt and Speed (2002). The F-statistics `F` are computed by `classifyTestsF` with `fstat.only=TRUE`.

`eBayes` does not compute ordinary t-statistics because they always have worse performance than the moderated versions. The ordinary (unmoderated) t-statistics can, however, can be easily extracted from the linear model output for comparison purposes—see the example code below.

`treat` computes empirical Bayes moderated-t p-values relative to a minimum meaningful fold-change threshold. Instead of testing for genes that have true log<sub>2</sub>-fold-changes different from zero, it tests whether the true log<sub>2</sub>-fold-change is greater than `lfc` in absolute value (McCarthy and Smyth, 2009). In other words, it uses an interval null hypothesis, where the interval is `[-lfc,lfc]`. When the number of DE genes is large, `treat` is often useful for giving preference to larger fold-changes and for prioritizing genes that are biologically important. `treat` is concerned with p-values rather than posterior odds, so it does not compute the B-statistic `lods`. The idea of thresholding doesn't apply to F-statistics in a straightforward way, so moderated F-statistics are also not computed. When `lfc=0`, `treat` is identical to `eBayes`, except that F-statistics and B-statistics are not computed. The `lfc` threshold is usually chosen relatively small, because significantly DE genes must all have fold changes substantially greater than the testing threshold. Typical values for `lfc` are  $\log_2(1.1)$ ,  $\log_2(1.2)$  or  $\log_2(1.5)$ . The top genes chosen by `treat` can be examined using `topTreat`.

Note that the `lfc` testing threshold used by `treat` to the define the null hypothesis is not the same as a log<sub>2</sub>-fold-change cutoff, as the observed log<sub>2</sub>-fold-change needs to be substantially larger than `lfc`

for the gene to be called as significant. In practice, modest values for `lfc` such as  $\log_2(1.1)$ ,  $\log_2(1.2)$  or  $\log_2(1.5)$  are usually the most useful. In practice, setting `lfc=log2(1.2)` or `lfc=log2(1.5)` will usually cause most differentially expressed genes to have estimated fold-changes of 2-fold or greater, depending on the sample size and precision of the experiment.

The use of `eBayes` or `treat` with `trend=TRUE` is known as the *limma-trend* method (Law et al, 2014; Phipson et al, 2016). With this option, an intensity-dependent trend is fitted to the prior variances `s2.prior`. Specifically, `squeezeVar` is called with the covariate equal to `Amean`, the average  $\log_2$ -intensity for each gene. The trend that is fitted can be examined by `plotSA`. *limma-trend* is useful for processing expression values that show a mean-variance relationship. This is often useful for microarray data, and it can also be applied to RNA-seq counts that have been converted to  $\log_2$ -counts per million (`logCPM`) values (Law et al, 2014). When applied to RNA-seq `logCPM` values, *limma-trend* give similar results to the `voom` method. The `voom` method incorporates the mean-variance trend into the precision weights, whereas *limma-trend* incorporates the trend into the empirical Bayes moderation. *limma-trend* is somewhat simpler than `voom` because it assumes that the sequencing depths (library sizes) are not wildly different between the samples and it applies the mean-variance trend on a genewise basis instead to individual observations. *limma-trend* is recommended for RNA-seq analysis when the library sizes are reasonably consistent (less than 3-fold difference from smallest to largest) because of its simplicity and speed.

If `robust=TRUE` then the robust empirical Bayes procedure of Phipson et al (2016) is used. This is frequently useful to protect the empirical Bayes procedure against hyper-variable or hypo-variable genes, especially when analysing RNA-seq data. See `squeezeVar` for more details.

## Value

`eBayes` produces an object of class `MArrayLM` (see `MArrayLM-class`) containing everything found in `fit` plus the following added components:

<code>t</code>	numeric vector or matrix of moderated t-statistics
<code>p.value</code>	numeric vector of p-values corresponding to the t-statistics
<code>s2.prior</code>	estimated prior value for $\sigma^2$ . A vector if covariate is non-NULL, otherwise a scalar.
<code>df.prior</code>	degrees of freedom associated with <code>s2.prior</code>
<code>df.total</code>	numeric vector of total degrees of freedom associated with t-statistics and p-values. Equal to <code>df.prior+df.residual</code> or <code>sum(df.residual)</code> , whichever is smaller.
<code>s2.post</code>	numeric vector giving the posterior values for $\sigma^2$
<code>lods</code>	numeric vector or matrix giving the log-odds of differential expression (natural log scale).
<code>var.prior</code>	estimated prior value for the variance of the $\log_2$ -fold-change for differentially expressed gene
<code>F</code>	numeric vector of moderated F-statistics for testing all contrasts defined by the columns of <code>fit</code> simultaneously equal to zero
<code>F.p.value</code>	numeric vector giving p-values corresponding to <code>F</code>

`treat` produces an `MArrayLM` object similar to `eBayes` but without `lods`, `var.prior`, `F` or `F.p.value`.

## Note

The algorithm used by `eBayes` and `treat` with `robust=TRUE` was revised slightly in `limma` 3.27.6. The minimum `df.prior` returned may be slightly smaller than previously.

*Empirical Bayes Statistics for Differential Expression (Deprecated)*

---

### Description

Given a microarray linear model fit, compute moderated t-statistics, moderated F-statistic, and log-odds of differential expression by empirical Bayes moderation of the standard errors towards a common value. This function is now deprecated. Please use [eBayes](#) instead.

### Usage

```
ebayes(fit, proportion=0.01, stdev.coef.lim=c(0.1,4),
       trend=FALSE, robust=FALSE, winsor.tail.p=c(0.05,0.1))
```

### Arguments

fit	an MArrayLM fitted model object produced by <code>lmFit</code> or <code>contrasts.fit</code> . For <code>ebayes</code> only, <code>fit</code> can alternatively be an unclassed list produced by <code>lm.series</code> , <code>gls.series</code> or <code>mrlm</code> containing components <code>coefficients</code> , <code>stdev.unscaled</code> , <code>sigma</code> and <code>df.residual</code> .
proportion	numeric value between 0 and 1, assumed proportion of genes which are differentially expressed
stdev.coef.lim	numeric vector of length 2, assumed lower and upper limits for the standard deviation of log2-fold-changes for differentially expressed genes
trend	logical, should an intensity-trend be allowed for the prior variance? Default is that the prior variance is constant.
robust	logical, should the estimation of <code>df.prior</code> and <code>var.prior</code> be robustified against outlier sample variances?
winsor.tail.p	numeric vector of length 1 or 2, giving left and right tail proportions of <code>x</code> to Winsorize. Used only when <code>robust=TRUE</code> .

### Details

This function is now deprecated. Please use [eBayes](#) instead.

### Value

A list with components:

t	numeric vector or matrix of moderated t-statistics
p.value	numeric vector of p-values corresponding to the t-statistics
s2.prior	estimated prior value for $\sigma^2$ . A vector if <code>covariate</code> is non-NULL, otherwise a scalar.
df.prior	degrees of freedom associated with <code>s2.prior</code>
df.total	numeric vector of total degrees of freedom associated with t-statistics and p-values. Equal to <code>df.prior+df.residual</code> or <code>sum(df.residual)</code> , whichever is smaller.
s2.post	numeric vector giving the posterior values for $\sigma^2$

lods	numeric vector or matrix giving the log-odds of differential expression (natural log scale).
var.prior	estimated prior value for the variance of the log <sub>2</sub> -fold-change for differentially expressed gene

---

EList-class*Expression List - class*

---

**Description**

A list-based S4 classes for storing expression values (E-values), for example for a set of one-channel microarrays or a set of RNA-seq samples. EListRaw holds expression values on the raw scale. EList holds expression values on the log scale, usually after background correction and normalization.

EListRaw objects are often created by [read.maimages](#), while EList objects are often created by [normalizeBetweenArrays](#) or by [voom](#). Alternatively, an EList object can be created directly by `new("EList", x)`, where x is a list.

**Required Components**

These classes contains no slots (other than `.Data`), but objects should contain a list component E:

E numeric matrix containing expression values. In an EListRaw object, the expression values are unlogged, while in an EList object, they are log<sub>2</sub> values. Rows correspond to probes and columns to samples.

**Optional Components**

Optional components include:

Eb numeric matrix containing unlogged background expression values, of same dimensions as E. For an EListRaw object only.

`weights` numeric matrix of same dimensions as `E` containing relative spot quality weights. Elements should be non-negative.

`other` list containing other matrices, all of the same dimensions as `E`.

`genes` data.frame containing probe information. Should have one row for each probe. May have any number of columns.

`targets` data.frame containing information on the target RNA samples. Rows correspond to samples. May have any number of columns.

Valid `EList` or `EListRaw` objects may contain other optional components, but all probe or sample information should be contained in the above components.

## Methods

These classes inherit directly from class `list` so any operation appropriate for lists will work on objects of this class. In addition, `EList` objects can be [subsetting](#) and [combined](#). `EList` objects will return dimensions and hence functions such as `dim`, `nrow` and `ncol` are defined. `ELists` also inherit a `show` method from the virtual class `LargeDataObject`, which means that `ELists` will print in a compact way.

## Author(s)

Gordon Smyth

`ExpressionSet` is a more formal class in the `Biobase` package used for the same purpose.

---

exprs.MA

*Extract Log-Expression Matrix from MAList*

---

## Description

Extract the matrix of log-expression values from an `MAList` object.

## Usage

```
exprs.MA(MA)
```

## Arguments

`MA` an `MAList` object.

## Details

Converts `M` and `A`-values to log-expression values. The output matrix will have two columns for each array, in the order green, red for each array.

This contrasts with `as.matrix.MAList` which extracts the `M`-values only, or `RG.MA` which converts to expression values in `RGList` form.

**Value**

A numeric matrix with twice the columns of the input.

**Author(s)**

Gordon Smyth

[02.Classes](#) gives an overview of data classes used in LIMMA.

---

fitFDist

*Moment Estimation of Scaled F-Distribution*

---

**Description**

Moment estimation of the parameters of a scaled F-distribution given one of the degrees of freedom. This function is called internally by eBayes and squeezeVar and is not usually called directly by a user.

**Usage**

```
fitFDist(x, df1, covariate=NULL)
fitFDistRobustly(x, df1, covariate=NULL, winsor.tail.p=c(0.05,0.1), trace=FALSE)
```

**Arguments**

x	numeric vector or array of positive values representing a sample from a scaled F-distribution.
df1	the first degrees of freedom of the F-distribution. Can be a single value, or else a vector of the same length as x.
covariate	if non-NULL, the estimated scale value will depend on this numeric covariate.
winsor.tail.p	numeric vector of length 1 or 2, giving left and right tail proportions of x to Winsorize.
trace	logical value indicating whether a trace of the iteration progress should be printed.

**Details**

fitFDist implements an algorithm proposed by Smyth (2004) and Phipson et al (2016). It estimates scale and df2 under the assumption that x is distributed as scale times an F-distributed random variable on df1 and df2 degrees of freedom. The parameters are estimated using the method of moments, specifically from the mean and variance of the x values on the log-scale.

When covariate is supplied, a spline curve trend will be estimated for the x values and the estimation will be adjusted for this trend (Phipson et al, 2016).

fitFDistRobustly is similar to fitFDist except that it computes the moments of the Winsorized values of x, making it robust against left and right outliers. Larger values for winsor.tail.p produce more robustness but less efficiency. When covariate is supplied, a loess trend is estimated for the x values. The robust method is described by Phipson et al (2016).

As well as estimating the F-distribution for the bulk of the cases, i.e., with outliers discounted, fitFDistRobustly also returns an estimated F-distribution with reduced df2 that might be appropriate for each outlier case.

**Value**

fitFDist produces a list with the following components:

scale	scale factor for F-distribution. A vector if covariate is non-NULL, otherwise a scalar.
df2	the second degrees of freedom of the fitted F-distribution.

fitFDistRobustly returns the following components as well:

tail.p.value	right tail probability of the scaled F-distribution for each x value.
prob.outlier	posterior probability that each case is an outlier relative to the scaled F-distribution with degrees of freedom df1 and df2.
df2.outlier	the second degrees of freedom associated with extreme outlier cases.
df2.shrunk	numeric vector of values for the second degrees of freedom, with shrunk values for outliers. Most values are equal to df2, but outliers have reduced values depending on how extreme each case is. All values lie between df2.outlier and df2.

**Note**

The algorithm used by fitFDistRobustly was revised slightly in limma 3.27.6. The prob.outlier value, which is the lower bound for df2.shrunk, may be slightly smaller than previously.

fitGammaIntercept      *Fit Intercept to Vector of Gamma Distributed Variates*

---

### Description

Fit Intercept to Vector of Gamma Distributed Variates

### Usage

```
fitGammaIntercept(y,offset=0,maxit=1000)
```

### Arguments

y	numeric vector of positive response values.
offset	numeric vector giving known part of the expected value of y. Can be a single value, or else a vector of the same length as y.
maxit	maximum number of Newton iterations to be done.

### Details

The values y are assumed to follow a gamma distribution with common shape parameter and with expected values given by  $x+offset$ . The function implements a globally convergent Newton iteration to estimate x.

### Value

Numeric value giving intercept.

### Author(s)

Gordon Smyth and Belinda Phipson

### References

x <- 9
mu <- x+offset
y <- rgamma(10,shape=20,scale=mu/20)
fitGammaIntercept(y,offset=offset)
```

fitmixture

*Fit Mixture Model by Non-Linear Least Squares***Description**

Fit Mixture Model by Non-Linear Least Squares

**Usage**

```
fitmixture(log2e, mixprop, niter = 4, trace = FALSE)
```

**Arguments**

log2e	a numeric matrix containing log2 expression values. Rows correspond to probes for genes and columns to RNA samples.
mixprop	a vector of length ncol(log2e) giving the mixing proportion (between 0 and 1) for each sample.
niter	integer number of iterations.
trace	logical. If TRUE, summary working estimates are output from each iteration.

**Details**

A mixture experiment is one in which two reference RNA sources are mixed in different proportions to create experimental samples. Mixture experiments have been used to evaluate genomic technologies and analysis methods (Holloway et al, 2006). This function uses all the data for each gene to estimate the expression level of the gene in each of two pure samples.

The function fits a nonlinear mixture model to the log2 expression values for each gene. The expected values of log2e for each gene are assumed to be of the form  $\log_2(\text{mixprop} \cdot Y_1 + (1 - \text{mixprop}) \cdot Y_2)$  where  $Y_1$  and  $Y_2$  are the expression levels of the gene in the two reference samples being mixed. The mixprop values are the same for each gene but  $Y_1$  and  $Y_2$  are specific to the gene. The function returns the estimated values  $A = 0.5 \cdot \log_2(Y_1 \cdot Y_2)$  and  $M = \log_2(Y_2 / Y_1)$  for each gene.

The nonlinear estimation algorithm implemented in fitmixture uses a nested Gauss-Newton iteration (Smyth, 1996). It is fully vectorized so that the estimation is done for all genes simultaneously.

**Value**

List with three components:

A	numeric vector giving the estimated average log2 expression of the two reference samples for each gene
M	numeric vector giving estimated log-ratio of expression between the two reference samples for each gene
stdev	standard deviation of the residual term in the mixture model for each gene

## Description

Obtains fitted values from a fitted microarray linear model object.

## Usage

```
## S3 method for class 'MArrayLM'
fitted(object, ...)
```

## Arguments

object            a fitted object of class inheriting from "MArrayLM".  
 ...              other arguments are not currently used.

## Value

A numeric matrix of fitted values.

[fitted](#)

genas

*Genuine Association of Gene Expression Profiles***Description**

Calculates biological correlation between two gene expression profiles.

**Usage**

```
genas(fit, coef=c(1,2), subset="all", plot=FALSE, alpha=0.4)
```

**Arguments**

fit	an MArrayLM fitted model object produced by <code>lmFit</code> or <code>contrasts.fit</code> and followed by <code>eBayes</code> .
coef	numeric vector of length 2 indicating which columns in the fit object are to be correlated.
subset	character string indicating which subset of genes to include in the correlation analysis. Choices are "all", "Fpval", "p.union", "p.int", "logFC" or "predFC".
plot	logical, should a scatterplot be produced summarizing the correlation analysis?
alpha	numeric value between 0 and 1 determining the transparency of the technical and biological ellipses if a plot is produced. <code>alpha=0</code> indicates fully transparent and <code>alpha=1</code> indicates fully opaque.

**Details**

The function estimates the biological correlation between two different contrasts in a linear model. By biological correlation, we mean the correlation that would exist between the log<sub>2</sub>-fold changes (logFC) for the two contrasts, if measurement error could be eliminated and the true log-fold-changes were known. This function is motivated by the fact that different contrasts for a linear model are often strongly correlated in a technical sense. For example, the estimated logFC for multiple treatment conditions compared back to the same control group will be positively correlated even in the absence of any biological effect. This function aims to separate the biological from the technical components of the correlation. The method is explained briefly in Majewski et al (2010) and in full detail in Phipson (2013).

The `subset` argument specifies whether and how the fit object should be subsetted. Ideally, only genes that are truly differentially expressed for one or both of the contrasts should be used estimate the biological correlation. The default is "all", which uses all genes in the fit object to estimate the biological correlation. The option "Fpval" chooses genes based on how many F-test p-values are estimated to be truly significant using the function `propTrueNull`. This should capture genes that display any evidence of differential expression in either of the two contrasts. The options "p.union" and "p.int" are based on the moderated t p-values from both contrasts. From the `propTrueNull` function an estimate of the number of p-values truly significant in either of the two contrasts can be obtained. "p.union" takes the union of these genes and "p.int" takes the intersection of these genes. The other options, "logFC" and "predFC" subsets on genes that attain a logFC or predFC at least as large as the 90th percentile of the log fold changes or predictive log fold changes on the absolute scale.

The `plot` option is a logical argument that specifies whether or not to plot a scatter plot of log-fold-changes for the two contrasts. The biological and technical correlations are overlaid on the scatterplot using semi-transparent ellipses. `library(ellipse)` is required to enable the plotting of ellipses.

**Value**

genas produces a list with the following components:

technical.correlation	estimate of the technical correlation
biological.correlation	estimate of the biological correlation
covariance.matrix	estimate of the covariance matrix from which the biological correlation is obtained
deviance	the likelihood ratio test statistic used to test whether the biological correlation is equal to 0
p.value	the p.value associated with deviance
n	the number of genes used to estimate the biological correlation

**Note**

As present, genas assumes that technical correlations between coefficients are the same for all genes, and hence it only works with fit objects that were created without observation weights or missing values. It does not work with voom pipelines, because these involve observation weights.

---

geneSetTest

*Mean-rank Gene Set Test*

---

## Description

Test whether a set of genes is highly ranked relative to other genes in terms of a given statistic. Genes are assumed to be independent.

## Usage

```

geneSetTest(index, statistics, alternative = "mixed", type= "auto",
            ranks.only = TRUE, nsim=9999)
wilcoxGST(index, statistics, ...)

```

## Arguments

index	index vector for the gene set. This can be a vector of indices, or a logical vector of the same length as statistics or, in general, any vector such that statistic[index] gives the statistic values for the gene set to be tested.
statistics	vector, any genewise statistic by which genes can be ranked.
alternative	character string specifying the alternative hypothesis, must be one of "mixed", "either", "up" or "down". "two.sided", "greater" and "less" are also permitted as synonyms for "either", "up" and "down" respectively.
type	character string specifying whether the statistics are signed (t-like, "t") or unsigned (F-like, "f") or whether the function should make an educated guess ("auto"). If the statistic is unsigned, then it assume that larger statistics are more significant.
ranks.only	logical, if TRUE only the ranks of the statistics are used.
nsim	number of random samples to take in computing the p-value. Not used if ranks.only=TRUE.
...	other arguments are passed to geneSetTest.

## Details

These functions compute a p-value to test the hypothesis that the indexed test set of genes tends to be more highly ranked in terms of some test statistic compared to randomly chosen genes. The statistic might be any statistic of interest, for example a t-statistic or F-statistic for differential expression. Like all gene set tests, these functions can be used to detect differential expression for a group of genes, even when the effects are too small or there is too little data to detect the genes individually.

`wilcoxGST` is a synonym for `geneSetTest` with `ranks.only=TRUE`. This version of the test procedure was developed by Michaud et al (2008), who called it *mean-rank gene-set enrichment*.

`geneSetTest` performs a *competitive* test in the sense that genes in the test set are compared to other genes (Goeman and Buhlmann, 2007). If the statistic is a genewise test statistic for differential expression, then `geneSetTest` tests whether genes in the set are more differentially expressed than genes not in the set. By contrast, a *self-contained* gene set test such as `roast` tests whether genes in the test set are differentially expressed, in an absolute sense, without regard to any other genes on the array.

Because it is based on permuting genes, `geneSetTest` assumes that the different genes (or probes) are statistically independent. (Strictly speaking, it assumes that the genes in the set are no more correlated on average than randomly chosen genes.) If inter-gene correlations are present, then a statistically significant result from `geneSetTest` indicates either that the set is highly ranked or that the genes in the set are positively correlated on average (Wu and Smyth, 2012). Unless gene sets with positive correlations are particularly of interest, it may be advisable to use `camera` or `cameraPR` instead to adjust the test for inter-gene correlations. Inter-gene correlations are likely to be present in differential expression experiments with biologically heterogeneous experimental units. On the other hand, the assumption of independence between genes should hold when the replicates are purely technical, i.e., when there is no biological variability between the replicate arrays in each experimental condition.

The statistics are usually a set of probe-wise statistics arising for some comparison from a microarray experiment. They may be t-statistics, meaning that the genewise null hypotheses would be rejected for large positive or negative values, or they may be F-statistics, meaning that only large values are significant. Any set of signed statistics, such as log-ratios, M-values or moderated t-statistics, are treated as t-like. Any set of unsigned statistics, such as F-statistics, posterior probabilities or chi-square tests are treated as F-like. If `type="auto"` then the statistics will be taken to be t-like if they take both positive and negative values and will be taken to be F-like if they are all of the same sign.

There are four possible alternatives to test for. `alternative=="up"` means the genes in the set tend to be up-regulated, with positive t-statistics. `alternative=="down"` means the genes in the set tend to be down-regulated, with negative t-statistics. `alternative=="either"` means the set is either up or down-regulated as a whole. `alternative=="mixed"` test whether the genes in the set tend to be differentially expressed, without regard for direction. In this case, the test will be significant if the set contains mostly large test statistics, even if some are positive and some are negative.

The latter three alternatives are appropriate when there is a prior expectation that all the genes in the set will react in the same direction. The "mixed" alternative is appropriate if you know only that the genes are involved in the relevant pathways, possibly in different directions. The "mixed" is the only meaningful alternative with F-like statistics.

The test statistic used for the gene-set-test is the mean of the statistics in the set. If `ranks.only` is TRUE the only the ranks of the statistics are used. In this case the p-value is obtained from a Wilcoxon test. If `ranks.only` is FALSE, then the p-value is obtained by simulation using `nsim` random sets of genes.

**Value**

numeric value giving the estimated p-value.

**Note**

Wu and Smyth (2012) show that `geneSetTest` does not does correct for inter-gene correlations and is more likely to assign small p-values to sets containing positive correlated genes. The function `cameraPR` is recommended as a alternative.

getEAWP

*Extract Basic Data from Expression Data Objects*

---

**Description**

Given an expression data object of any known class, get the expression values, weights, probe annotation and A-values that are needed for linear modelling. This function is called by the linear modelling functions in LIMMA.

**Usage**

```
getEAWP(object)
```

**Arguments**

**object** any matrix-like object containing log-expression values. Can be an object of class `MAList`, `EList`, `marrayNorm`, `PLMset`, `vsn`, or any class inheriting from `ExpressionSet`, or any object that can be coerced to a numeric matrix.

**Details**

Rows correspond to probes and columns to RNA samples.

In the case of two-color microarray data objects (`MAList` or `marrayNorm`), `Amean` is the vector of row means of the matrix of A-values. For other data objects, `Amean` is the vector of row means of the matrix of expression values.

From April 2013, the rownames of the output `exprs` matrix are required to be unique. If `object` has no row names, then the output rownames of `exprs` are `1:nrow(object)`. If `object` has row names but with duplicated names, then the rownames of `exprs` are set to `1:nrow(object)` and the original row names are preserved in the ID column of probes.

`object` should be a normalized data object. `getEAWP` will return an error if `object` is a non-normalized data object such as `RGList` or `EListRaw`, because these do not contain log-expression values.

**Value**

A list with components

<code>exprs</code>	numeric matrix of log-ratios, log-intensities or log-expression values
<code>weights</code>	numeric matrix of weights
<code>probes</code>	<code>data.frame</code> of probe-annotation
<code>Amean</code>	numeric vector of average log-expression for each probe

`exprs` is the only required component. The other components will be `NULL` if not found in the input object.

---

getLayout

*Extract the Print Layout of an Array from the GAL File*

---

**Description**

From the Block, Row and Column information in a `genelist`, determine the number of grid rows and columns on the array and the number of spot rows and columns within each grid.

**Usage**

```
getLayout(gal, guessdups=FALSE)
getLayout2(galfile)
getDupSpacing(ID)
```

**Arguments**

gal	data.frame containing the GAL, i.e., giving the position and gene identifier of each spot
galfile	name or path of GAL file
guessdups	logical, if TRUE then try to determine number and spacing of duplicate spots, i.e., within-array replicates
ID	vector or factor of gene IDs

**Details**

A GenePix Array List (GAL) file is a list of genes and associated information produced by an Axon microarray scanner. The function `getLayout` determines the print layout from a data frame created from a GAL file or gene list. The data.frame must contain columns `Block`, `Column` and `Row`. (The number of tip columns is assumed to be either one or four.)

On some arrays, each probe may be duplicated a number of times (`ndups`) at regular intervals (`spacing`) in the GAL file. `getDupSpacing` determines valid values for `ndups` and `spacing` from a vector of IDs. If `guessdups=TRUE`, then `getLayout` calls `getDupSpacing`.

The function `getLayout2` attempts to determine the print layout from the header information of an actual GAL file.

**Value**

A `printlayout` object, which is a list with the following components. The last two components are present only if `guessdups=TRUE`.

<code>ngrid.r</code>	integer, number of grid rows on the arrays
<code>ngrid.c</code>	integer, number of grid columns on the arrays
<code>nspot.r</code>	integer, number of rows of spots in each grid
<code>nspot.c</code>	integer, number of columns of spots in each grid
<code>ndups</code>	integer, number of times each probe is printed on the array
<code>spacing</code>	integer, spacing between multiple printings of each probe

**Author(s)**

**Examples**

```
# gal <- readGAL()
# layout <- getLayout(gal)
```

---

`getSpacing`*Get Numerical Spacing*

---

**Description**

Convert character to numerical spacing measure for within-array replicate spots.

**Usage**

```
getSpacing(spacing, layout)
```

**Arguments**

spacing	character string or integer. Acceptable character strings are "columns", "rows", "subarrays" or "topbottom". Integer values are simply passed through.
layout	list containing printer layout information

**Details**

"rows" means that duplicate spots are printed side-by-side by rows. These will be recorded in consecutive rows in the data object.

"columns" means that duplicate spots are printed side-by-side by columns. These will be separated in the data object by `layout$nspot.r` rows.

"subarrays" means that a number of sub-arrays, with identical probes in the same arrangement, are printed on each array. The spacing therefore will be the size of a sub-array.

"topbottom" is the same as "subarrays" when there are two sub-arrays.

**Value**

Integer giving spacing between replicate spots in the gene list.

**Author(s)**

Gordon Smyth

**See Also**

An overview of LIMMA functions for reading data is given in [03.ReadingData](#).

**Examples**

```
getSpacing("columns", list(ngrid.r=2, ngrid.c=2, nspot.r=20, nspot.c=19))
getSpacing("rows", list(ngrid.r=2, ngrid.c=2, nspot.r=20, nspot.c=19))
getSpacing("topbottom", list(ngrid.r=2, ngrid.c=2, nspot.r=20, nspot.c=19))
```

gls.series

*Fit Linear Model to Microarray Data by Generalized Least Squares***Description**

Fit a linear model genewise to expression data from a series of microarrays. The fit is by generalized least squares allowing for correlation between duplicate spots or related arrays. This is a utility function for `lmFit`.

**Usage**

```
gls.series(M, design=NULL, ndups=2, spacing=1, block=NULL, correlation=NULL, weights=NULL, ...)
```

**Arguments**

<code>M</code>	numeric matrix containing log-ratio or log-expression values for a series of microarrays, rows correspond to genes and columns to arrays.
<code>design</code>	numeric design matrix defining the linear model, with rows corresponding to arrays and columns to comparisons to be estimated. The number of rows must match the number of columns of <code>M</code> . Defaults to the unit vector meaning that the arrays are treated as replicates.
<code>ndups</code>	positive integer giving the number of times each gene is printed on an array. <code>nrow(M)</code> must be divisible by <code>ndups</code> . Ignored if <code>block</code> is not <code>NULL</code> .
<code>spacing</code>	the spacing between the rows of <code>M</code> corresponding to duplicate spots, <code>spacing=1</code> for consecutive spots. Ignored if <code>block</code> is not <code>NULL</code> .
<code>block</code>	vector or factor specifying a blocking variable on the arrays. Same length as <code>ncol(M)</code> .
<code>correlation</code>	numeric value specifying the inter-duplicate or inter-block correlation.
<code>weights</code>	an optional numeric matrix of the same dimension as <code>M</code> containing weights for each spot. If it is of different dimension to <code>M</code> , it will be filled out to the same size.
<code>...</code>	other optional arguments to be passed to <code>dupcor.series</code> .

**Details**

This is a utility function used by the higher level function `lmFit`. Most users should not use this function directly but should use `lmFit` instead.

This function is for fitting gene-wise linear models when some of the expression values are correlated. The correlated groups may arise from replicate spots on the same array (duplicate spots) or from a biological or technical replicate grouping of the arrays. This function is normally called by `lmFit` and is not normally called directly by users.

Note that the correlation is assumed to be constant across genes. If `correlation=NULL` then a call is made to `duplicateCorrelation` to estimate the correlation.

**Value**

A list with components

<code>coefficients</code>	numeric matrix containing the estimated coefficients for each linear model. Same number of rows as <code>M</code> , same number of columns as <code>design</code> .
<code>stdev.unscaled</code>	numeric matrix conformal with <code>coef</code> containing the unscaled standard deviations for the coefficient estimators. The standard errors are given by <code>stdev.unscaled * sigma</code> .
<code>sigma</code>	numeric vector containing the residual standard deviation for each gene.
<code>df.residual</code>	numeric vector giving the degrees of freedom corresponding to <code>sigma</code>
<code>correlation</code>	inter-duplicate or inter-block correlation
<code>qr</code>	QR decomposition of the generalized linear squares problem, i.e., the decomposition of <code>design</code> standardized by the Choleski-root of the correlation matrix defined by <code>correlation</code>

**Author(s)**

Gordon Smyth

[duplicateCorrelation](#).

An overview of linear model functions in `limma` is given by [06.LinearModels](#).

---

goana

*Gene Ontology or KEGG Pathway Analysis*

---

**Description**

Test for over-representation of gene ontology (GO) terms or KEGG pathways in one or more sets of genes, optionally adjusting for abundance or gene length bias.

**Usage**

```
## S3 method for class 'MArrayLM'
goana(de, coef = ncol(de), geneid = rownames(de), FDR = 0.05, trend = FALSE, ...)
## S3 method for class 'MArrayLM'
kegga(de, coef = ncol(de), geneid = rownames(de), FDR = 0.05, trend = FALSE, ...)
## Default S3 method:
goana(de, universe = NULL, species = "Hs", prior.prob = NULL, covariate=NULL,
      plot=FALSE, ...)
## Default S3 method:
kegga(de, universe = NULL, restrict.universe = FALSE, species = "Hs", species.KEGG = NULL,
      convert = FALSE, gene.pathway = NULL, pathway.names = NULL,
      prior.prob = NULL, covariate=NULL, plot=FALSE, ...)
getGeneKEGGLinks(species.KEGG = "hsa", convert = FALSE)
getKEGGPathwayNames(species.KEGG = NULL, remove.qualifier = FALSE)
```

**Arguments**

<code>de</code>	a character vector of Entrez Gene IDs, or a list of such vectors, or an MArrayLM fit object.
<code>coef</code>	column number or column name specifying for which coefficient or contrast differential expression should be assessed.
<code>geneid</code>	Entrez Gene identifiers. Either a vector of length <code>nrow(de)</code> or the name of the column of <code>de\$genes</code> containing the Entrez Gene IDs.
<code>FDR</code>	false discovery rate cutoff for differentially expressed genes. Numeric value between 0 and 1.
<code>species</code>	character string specifying the species. Possible values include "Hs" (human), "Mm" (mouse), "Rn" (rat), "Dm" (fly) or "Pt" (chimpanzee), but other values are possible if the corresponding organism package is available. See <a href="#">alias2Symbol</a> for other possible values. Ignored if <code>species.KEGG</code> or is not NULL or if <code>gene.pathway</code> and <code>pathway.names</code> are not NULL.
<code>species.KEGG</code>	three-letter KEGG species identifier. See <a href="http://www.kegg.jp/kegg/catalog/org_list.html">http://www.kegg.jp/kegg/catalog/org_list.html</a> or <a href="http://rest.kegg.jp/list/organism">http://rest.kegg.jp/list/organism</a> for possible values. Alternatively, if <code>de</code> contains KEGG ortholog IDs ("k00001" etc) instead of gene IDs, then set <code>species.KEGG="ko"</code> . This argument is ignored if <code>gene.pathway</code> and <code>pathway.names</code> are both not NULL.
<code>convert</code>	if TRUE then KEGG gene identifiers will be converted to NCBI Entrez Gene identifiers. Note that KEGG IDs are the same as Entrez Gene IDs for most species anyway.
<code>gene.pathway</code>	data.frame linking genes to pathways. First column gives gene IDs, second column gives pathway IDs. By default this is obtained automatically by <code>getGeneKEGGLinks(species.K)</code>
<code>remove.qualifier</code>	if TRUE, the species qualifier will be removed from the pathway names.
<code>pathway.names</code>	data.frame giving full names of pathways. First column gives pathway IDs, second column gives pathway names. By default this is obtained automatically using <code>getKEGGPathwayNames(species.KEGG, remove=TRUE)</code> .
<code>trend</code>	adjust analysis for gene length or abundance? Can be logical, or a numeric vector of covariate values, or the name of the column of <code>de\$genes</code> containing the covariate values. If TRUE, then <code>de\$Amean</code> is used as the covariate.
<code>universe</code>	vector specifying the set of Entrez Gene identifiers to be the background universe. If NULL then all Entrez Gene IDs associated with any gene ontology term will be used as the universe.
<code>restrict.universe</code>	logical, should the universe be restricted to gene identifiers found in at least one pathway in <code>gene.pathway</code> ?
<code>prior.prob</code>	optional numeric vector of the same length as <code>universe</code> giving the prior probability that each gene in the universe appears in a gene set. Will be computed from <code>covariate</code> if the latter is provided. Ignored if <code>universe</code> is NULL.
<code>covariate</code>	optional numeric vector of the same length as <code>universe</code> giving a covariate against which <code>prior.prob</code> should be computed. Ignored if <code>universe</code> is NULL.
<code>plot</code>	logical, should the <code>prior.prob</code> vs <code>covariate</code> trend be plotted?
<code>...</code>	any other arguments in a call to the MArrayLM methods are passed to the corresponding default method.

## Details

These functions perform over-representation analyses for Gene Ontology terms or KEGG pathways. The default methods accept a gene set as a vector of Entrez Gene IDs or multiple gene sets as a list of such vectors. An over-representation analysis is then done for each set. The `MArrayLM` method extracts the gene sets automatically from a linear model fit object.

The p-values returned by `goana` and `kegga` are unadjusted for multiple testing. The authors have chosen not to correct automatically for multiple testing because GO terms and KEGG pathways are often overlapping, so standard methods of p-value adjustment may be very conservative. Users should be aware though that p-values are unadjusted, meaning that only very small p-values should be used for published results.

`goana` uses annotation from the appropriate Bioconductor organism package. The species can be any character string `XX` for which an organism package `org.XX.eg.db` is installed. Examples are "Hs" for human for "Mm" for mouse. See [alias2Symbol](#) for other possible values for species.

`kegga` reads KEGG pathway annotation from the KEGG website. For `kegga`, the species name can be provided in either Bioconductor or KEGG format. Examples of KEGG format are "hsa" for human, "mmu" for mouse or "dme" for fly. `kegga` can be used for any species supported by KEGG, of which there are more than 14,000 possibilities. By default, `kegga` obtains the KEGG annotation for the specified species from the <http://rest.kegg.jp> website. Alternatively one can supply the required pathway annotation to `kegga` in the form of two `data.frames`. If this is done, then an internet connection is not required.

The gene ID system used by `kegga` for each species is determined by KEGG. For human and mouse, the default (and only choice) is Entrez Gene ID. For *Drosophila*, the default is FlyBase CG annotation symbol. The format of the IDs can be seen by typing `head(getGeneKEGGLinks(species))`, for example `head(getGeneKEGGLinks("hsa"))` or `head(getGeneKEGGLinks("dme"))`. Entrez Gene IDs can always be used. If Entrez Gene IDs are not the default, then conversion can be done by specifying `"convert=TRUE"`.

Another possibility is to use KEGG orthology IDs as the gene IDs, and these can be used for any species. In that case, set `species.KEGG="ko"`.

The ability to supply `data.frame` annotation to `kegga` means that `kegga` can in principle be used in conjunction with any user-supplied set of annotation terms.

The default `goana` and `kegga` methods accept a vector `prior.prob` giving the prior probability that each gene in the universe appears in a gene set. This vector can be used to correct for unwanted trends in the differential expression analysis associated with gene length, gene abundance or any other covariate (Young et al, 2010). The `MArrayLM` object computes the `prior.prob` vector automatically when `trend` is non-NULL.

If `prior.prob=NULL`, the function computes one-sided hypergeometric tests equivalent to Fisher's exact test. If prior probabilities are specified, then a test based on the Wallenius' noncentral hypergeometric distribution is used to adjust for the relative probability that each gene will appear in a gene set, following the approach of Young et al (2010).

The `MArrayLM` methods performs over-representation analyses for the up and down differentially expressed genes from a linear model analysis. In this case, the universe is all the genes found in the fit object.

`trend=FALSE` is equivalent to `prior.prob=NULL`. If `trend=TRUE` or a covariate is supplied, then a trend is fitted to the differential expression results and this is used to set `prior.prob`.

The statistical approach provided here is the same as that provided by the `goseq` package, with one methodological difference and a few restrictions. Unlike the `goseq` package, the gene identifiers here must be Entrez Gene IDs and the user is assumed to be able to supply gene lengths if necessary. The `goseq` package has additional functionality to convert gene identifiers and to provide gene lengths. The only methodological difference is that `goana` and `kegga` computes gene

length or abundance bias using `tricubeMovingAverage` instead of monotonic regression. While `tricubeMovingAverage` does not enforce monotonicity, it has the advantage of numerical stability when de contains only a small number of genes.

### Value

The goana default method produces a data frame with a row for each GO term and the following columns:

Term	GO term.
Ont	ontology that the GO term belongs to. Possible values are "BP", "CC" and "MF".
N	number of genes in the GO term.
DE	number of genes in the DE set.
P.DE	p-value for over-representation of the GO term in the set.

The last two column names above assume one gene set with the name DE. In general, there will be a pair of such columns for each gene set and the name of the set will appear in place of "DE".

The goana method for MArrayLM objects produces a data frame with a row for each GO term and the following columns:

Term	GO term.
Ont	ontology that the GO term belongs to. Possible values are "BP", "CC" and "MF".
N	number of genes in the GO term.
Up	number of up-regulated differentially expressed genes.
Down	number of down-regulated differentially expressed genes.
P.Up	p-value for over-representation of GO term in up-regulated genes.
P.Down	p-value for over-representation of GO term in down-regulated genes.

The row names of the data frame give the GO term IDs.

The output from `kegga` is the same except that row names become KEGG pathway IDs, Term becomes Pathway and there is no Ont column.

### Note

`kegga` requires an internet connection unless `gene.pathway` and `pathway.names` are both supplied.

The default for `kegga` with `species="Dm"` changed from `convert=TRUE` to `convert=FALSE` in `limma` 3.27.8. Users wanting to use Entrez Gene IDs for *Drosophila* should set `convert=TRUE`, otherwise fly-base CG annotation symbol IDs are assumed (for example "Dmel\_CG4637").

The default for `restrict.universe=TRUE` in `kegga` changed from `TRUE` to `FALSE` in `limma` 3.33.4.

Bug fix: results from `kegga` with `trend=TRUE` or with non-NULL covariate were incorrect prior to `limma` 3.32.3. The results were biased towards significant Down p-values and against significant Up p-values.

The goseq package provides an alternative implementation of methods from Young et al (2010). Unlike the limma functions documented here, goseq will work with a variety of gene identifiers and includes a database of gene length information for various species.

The gostat package also does GO analyses without adjustment for bias but with some other options.

See [10.GeneSetTests](#) for a description of other functions used for gene set testing.

**Examples**

```
## Not run:
## Linear model usage:

fit <- lmFit(y, design)
fit <- eBayes(fit)

# Standard GO analysis

go.fisher <- goana(fit, species="Hs")
topGO(go.fisher, sort = "up")
topGO(go.fisher, sort = "down")

# GO analysis adjusting for gene abundance

go.abund <- goana(fit, geneid = "GeneID", trend = TRUE)
topGO(go.abund, sort = "up")
topGO(go.abund, sort = "down")

# GO analysis adjusting for gene length bias
# (assuming that y$genes$Length contains gene lengths)

go.len <- goana(fit, geneid = "GeneID", trend = "Length")
topGO(go.len, sort = "up")
topGO(go.len, sort = "down")

## Default usage with a list of gene sets:

go.de <- goana(list(DE1 = EG.DE1, DE2 = EG.DE2, DE3 = EG.DE3))
topGO(go.de, sort = "DE1")
topGO(go.de, sort = "DE2")
topGO(go.de, ontology = "BP", sort = "DE3")
topGO(go.de, ontology = "CC", sort = "DE3")
topGO(go.de, ontology = "MF", sort = "DE3")

## Standard KEGG analysis

k <- kegg(fit, species="Hs")
k <- kegg(fit, species.KEGG="hsa") # equivalent to previous
topKEGG(k, sort = "up")
topKEGG(k, sort = "down")

## End(Not run)
```

---

gridr	<i>Row and Column Positions on Microarray</i>
-------	---

---

**Description**

Grid and spot row and column positions.

**Usage**

```
gridr(layout)
gridc(layout)
spotr(layout)
spotc(layout)
```

**Arguments**

layout            list with the components ngrid.r, ngrid.c, nspot.r and nspot.c

**Value**

Vector of length `prod(unlist(layout))` giving the grid rows (`gridr`), grid columns (`gridc`), spot rows (`spotr`) or spot columns (`spotc`).

**Author(s)**

Gordon Smyth

---

heatdiagram	<i>Stemmed Heat Diagram</i>
-------------	-----------------------------

---

**Description**

Creates a heat diagram showing the co-regulation of genes under one condition with a range of other conditions.

**Usage**

```
heatDiagram(results, coef, primary=1, names=NULL, treatments=colnames(coef), limit=NULL,
             orientation="landscape", low="green", high="red", cex=1, mar=NULL,
             ncolors=123, ...)
heatdiagram(stat, coef, primary=1, names=NULL, treatments=colnames(stat),
             critical.primary=4, critical.other=3, limit=NULL, orientation="landscape",
             low="green", high="red", cex=1, mar=NULL, ncolors=123, ...)
```

**Arguments**

<code>results</code>	TestResults matrix, containing elements -1, 0 or 1, from <code>decideTests</code>
<code>stat</code>	numeric matrix of test statistics. Rows correspond to genes and columns to treatments or contrasts between treatments.
<code>coef</code>	numeric matrix of the same size as <code>stat</code> . Holds the coefficients to be displayed in the plot.
<code>primary</code>	number or name of the column to be compared to the others. Genes are included in the diagram according to this column of <code>stat</code> and are sorted according to this column of <code>coef</code> . If <code>primary</code> is a name, then <code>stat</code> and <code>coef</code> must have the same column names.
<code>names</code>	optional character vector of gene names
<code>treatments</code>	optional character vector of treatment names
<code>critical.primary</code>	critical value above which the test statistics for the primary column are considered significant and included in the plot
<code>critical.other</code>	critical value above which the other test statistics are considered significant. Should usually be no larger than <code>critical.primary</code> although larger values are permitted.
<code>limit</code>	optional value for <code>coef</code> above which values will be plotted in extreme color. Defaults to <code>max(abs(coef))</code> .
<code>orientation</code>	"portrait" for upright plot or "landscape" for plot orientated to be wider than high. "portrait" is likely to be appropriate for inclusion in printed document while "landscape" may be appropriate for a presentation on a computer screen.
<code>low</code>	color associated with repressed gene regulation
<code>high</code>	color associated with induced gene regulation
<code>ncolors</code>	number of distinct colors used for each of up and down regulation
<code>cex</code>	factor to increase or decrease size of column and row text
<code>mar</code>	numeric vector of length four giving the size of the margin widths. Default is <code>cex*c(5, 6, 1, 1)</code> for landscape and <code>cex*c(1, 1, 4, 3)</code> for portrait.
<code>...</code>	any other arguments will be passed to the <code>image</code> function

**Details**

Users are encouraged to use `heatDiagram` rather than `heatdiagram` as the later function may be removed in future versions of `limma`.

This function plots an image of gene expression profiles in which rows (or columns for portrait orientation) correspond to treatment conditions and columns (or rows) correspond to genes. Only genes which are significantly differentially expressed in the primary condition are included. Genes are sorted by differential expression under the primary condition.

Note: the plot produced by this function is unique to the `limma` package. It should not be confused with "heatmaps" often used to display results from cluster analyses.

**Value**

An image is created on the current graphics device. A matrix with named rows containing the coefficients used in the plot is also invisibly returned.

**Author(s)**

Gordon Smyth

**See Also**[image.](#)**Examples**

```
## Not run:
MA <- normalizeWithinArrays(RG)
design <- cbind(c(1,1,1,0,0,0),c(0,0,0,1,1,1))
fit <- lmFit(MA,design=design)
contrasts.mouse <- cbind(Control=c(1,0),Mutant=c(0,1),Difference=c(-1,1))
fit <- eBayes(contrasts.fit(fit,contrasts=contrasts.mouse))
results <- decideTests(fit,method="global",p=0.1)
heatDiagram(results,fit$coef,primary="Difference")

## End(Not run)
```

---

helpMethods

*Prompt for Method Help Topics*

---

**Description**

For any S4 generic function, find all methods defined in currently loaded packages. Prompt the user to choose one of these to display the help document.

**Usage**

```
helpMethods(genericFunction)
```

**Arguments**

```
genericFunction
```

a generic function or a character string giving the name of a generic function

**Author(s)**

Gordon Smyth

**See Also**[showMethods](#)**Examples**

```
## Not run: helpMethods(show)
```

---

`ids2indices`*Convert Gene Identifiers to Indices for Gene Sets*

---

**Description**

Make a list of gene identifiers into a list of indices for gene sets.

**Usage**

```
ids2indices(gene.sets, identifiers, remove.empty=TRUE)
```

**Arguments**

<code>gene.sets</code>	list of character vectors, each vector containing the gene identifiers for a set of genes.
<code>identifiers</code>	character vector of gene identifiers.
<code>remove.empty</code>	logical, should sets of size zero be removed from the output?

**Details**

This function used to create input for `romer`, `mroast` and `camera` function. Typically, `identifiers` is the vector of Entrez Gene IDs, and `gene.sets` is obtained constructed from a database of gene sets, for example a representation of the Molecular Signatures Database (MSigDB) downloaded from <http://bioinf.wehi.edu.au/software/MSigDB>.

**Value**

list of integer vectors, each vector containing the indices of a gene set in the vector `identifiers`.

**Author(s)**

Gordon Smyth and Yifang Hu

**See Also**

[romer](#), [mroast](#), [camera](#)

There is a topic page on [10.GeneSetTests](#).

**Examples**

```
## Not run:

download.file("http://bioinf.wehi.edu.au/software/MSigDB/human_c2_v5p2.rdata",
             "human_c2_v5p2.rdata", mode = "wb")

load("human_c2_v5p2.rdata")
c2.indices <- ids2indices(Hs.c2, y$genes$GeneID)
camera(y, c2.indices, design)

## End(Not run)
```

imageplot

*Image Plot of Microarray Statistics***Description**

Creates an image of colors or shades of gray that represent the values of a statistic for each spot on a spotted microarray. This function can be used to explore any spatial effects across the microarray.

**Usage**

```
imageplot(z, layout, low = NULL, high = NULL, ncolors = 123, zerocenter = NULL,
zlim = NULL, mar=c(2,1,1,1), legend=TRUE, ...)
```

**Arguments**

z	numeric vector or array. This vector can contain any spot statistics, such as log intensity ratios, spot sizes or shapes, or t-statistics. Missing values are allowed and will result in blank spots on the image. Infinite values are not allowed.
layout	a list specifying the dimensions of the spot matrix and the grid matrix.
low	color associated with low values of z. May be specified as a character string such as "green", "white" etc, or as a rgb vector in which $c(1, 0, 0)$ is red, $c(0, 1, 0)$ is green and $c(0, 0, 1)$ is blue. The default value is "green" if zerocenter=T or "white" if zerocenter=F.
high	color associated with high values of z. The default value is "red" if zerocenter=T or "blue" if zerocenter=F.
ncolors	number of color shades used in the image including low and high.
zerocenter	should zero values of z correspond to a shade exactly halfway between the colors low and high? The default is TRUE if z takes positive and negative values, otherwise FALSE.
zlim	numerical vector of length 2 giving the extreme values of z to associate with colors low and high. By default zlim is the range of z. Any values of z outside the interval zlim will be truncated to the relevant limit.
mar	numeric vector of length 4 specifying the width of the margin around the plot. This argument is passed to <a href="#">par</a> .
legend	logical, if TRUE the range of z and zlim is shown in the bottom margin
...	any other arguments will be passed to the function image

**Details**

This function may be used to plot the values of any spot-specific statistic, such as the log intensity ratio, background intensity or a quality measure such as spot size or shape. The image follows the layout of an actual microarray slide with the bottom left corner representing the spot (1,1,1,1). The color range is used to represent the range of values for the statistic. When this function is used to plot the red/green log-ratios, it is intended to be an in silico version of the classic false-colored red-yellow-green image of a scanned two-color microarray.

This function is related to the earlier `plot.spatial` function in the `sma` package and to the later `maImage` function in the `marray` package. It differs from `plot.spatial` most noticeably in that all the spots are plotted and the image is plotted from bottom left rather than from top left. It is

intended to display spatial patterns and artefacts rather than to highlight only the extreme values as does `plot.spatial`. It differs from `maImage` in that any statistic may be plotted and in its use of a red-yellow-green color scheme for log-ratios, similar to the classic false-colored jpeg image, rather than the red-black-green color scheme associated with heat maps.

### Value

An plot is created on the current graphics device.

### Author(s)

Gordon Smyth

### See Also

`maImage` in the `marray` package, `image` in the `graphics` package.

An overview of diagnostic functions available in LIMMA is given in [09.Diagnostics](#).

### Examples

```
M <- rnorm(8*4*16*16)
imageplot(M, layout=list(ngrid.r=8, ngrid.c=4, nspot.r=16, nspot.c=16))
```

---

imageplot3by2

*Write Imageplots to Files*

---

### Description

Write imageplots to files in PNG format, six plots to a file in a 3 by 2 grid arrangement.

### Usage

```
imageplot3by2(RG, z="Gb", prefix=paste("image",z,sep="-"), path=NULL,
              xlim=NULL, common.lim=TRUE, ...)
```

### Arguments

<code>RG</code>	an <code>RGList</code> or <code>MAList</code> object, or any list with component named by <code>z</code>
<code>z</code>	character string giving name of component of <code>RG</code> to plot
<code>prefix</code>	character string giving prefix to attach to file names
<code>path</code>	character string specifying directory for output files
<code>xlim</code>	numeric vector of length 2, giving limits of response vector to be associated with saturated colors
<code>common.lim</code>	logical, should all plots on a page use the same axis limits
<code>...</code>	any other arguments are passed to <code>imageplot</code>

### Details

At the time of writing, this function writes plots in PNG format in an arrangement optimized for A4-sized paper.

**Value**

No value is returned, but one or more files are written to the working directory. The number of files is determined by the number of columns of RG.

**Author(s)**

Gordon Smyth

**See Also**

An overview of diagnostic functions available in LIMMA is given in [09.Diagnostics](#).

---

intraspotCorrelation *Intra-Spot Correlation for Two Color Data*

---

**Description**

Estimate the within-block correlation associated with spots for spotted two color microarray data.

**Usage**

```
intraspotCorrelation(object, design, trim=0.15)
```

**Arguments**

object	an <a href="#">MAList</a> object or a list from which M and A values may be extracted
design	a numeric matrix containing the design matrix for linear model in terms of the individual channels. The number of rows should be twice the number of arrays. The number of columns will determine the number of coefficients estimated for each gene.
trim	the fraction of observations to be trimmed from each end of the atanh-correlations when computing the consensus correlation. See <a href="#">mean</a> .

**Details**

This function estimates the correlation between two channels observed on each spot. The correlation is estimated by fitting a heteroscedastic regression model to the M and A-values of each gene. The function also returns a consensus correlation, which is a robust average of the individual correlations, which can be used as input for functions `lmscFit`.

The function may take long time to execute.

**Value**

A list with components

`consensus.correlation`

robust average of the estimated inter-duplicate correlations. The average is the trimmed mean of the correlations for individual genes on the atanh-transformed scale.

`atanh.correlations`

a numeric vector giving the individual genewise correlations on the atanh scale

df numeric matrix of degrees of freedom associated with the correlations. The first column gives the degrees of freedom for estimating the within-spot or M-value mean square while the second gives the degrees of freedom for estimating the between spot or A-value mean square.

### Author(s)

Gordon Smyth

### References

### See Also

This function uses [remlscore](#) from the statmod package.

An overview of methods for single channel analysis in limma is given by [07.SingleChannel](#).

### Examples

```
# See lmscFit
## Not run:
corfit <- intraspotCorrelation(MA, design)
all.correlations <- tanh(corfit$atanh.correlations)
boxplot(all.correlations)

## End(Not run)
```

---

is.fullrank

*Check for Full Column Rank*

---

### Description

Test whether a numeric matrix has full column rank.

### Usage

```
is.fullrank(x)
nonEstimable(x)
```

### Arguments

x a numeric matrix or vector

### Details

is.fullrank is used to check the integrity of design matrices in limma, for example after [subsetting](#) operations.

nonEstimable is used by [lmFit](#) to report which coefficients in a linear model cannot be estimated.

**Value**

is.fullrank returns TRUE or FALSE.

nonEstimable returns a character vector of names for the columns of x which are linearly dependent on previous columns. If x has full column rank, then the value is NULL.

**Author(s)**

Gordon Smyth

**Examples**

```
# TRUE
is.fullrank(1)
is.fullrank(cbind(1,0:1))

# FALSE
is.fullrank(0)
is.fullrank(matrix(1,2,2))
nonEstimable(matrix(1,2,2))
```

---

isNumeric

*Test for Numeric Argument*

---

**Description**

Test whether argument is numeric or a data.frame with numeric columns.

**Usage**

```
isNumeric(x)
```

**Arguments**

x                    any object

**Details**

This function is used to check the validity of arguments for numeric functions. It is an attempt to emulate the behavior of internal generic math functions.

isNumeric differs from is.numeric in that data.frames with all columns numeric are accepted as numeric.

**Value**

TRUE or FALSE

**Author(s)**

Gordon Smyth

**See Also**

[is.numeric](#), [Math](#)

**Examples**

```
isNumeric(3)
isNumeric("a")
x <- data.frame(a=c(1,1),b=c(0,1))
isNumeric(x) # TRUE
is.numeric(x) # FALSE
```

---

 kooperberg

---

*Kooperberg Model-Based Background Correction for GenePix data*

---

**Description**

This function uses a Bayesian model to background correct GenePix microarray data.

**Usage**

```
kooperberg(RG, a = TRUE, layout = RG$printer, verbose = TRUE)
```

**Arguments**

RG	an RGList of GenePix data, read in using <code>read.maimages</code> , with other <code>.columns=c("F635 SD", "B635 SD")</code>
a	logical. If TRUE, the 'a' parameters in the model (equation 3 and 4) are estimated for each slide. If FALSE the 'a' parameters are set to unity.
layout	list containing print layout with components <code>ngrid.r</code> , <code>ngrid.c</code> , <code>nspot.r</code> and <code>nspot.c</code> . Defaults to <code>RG\$printer</code> .
verbose	logical. If TRUE, progress is reported to standard output.

**Details**

This function is for use with GenePix data and is designed to cope with the problem of large numbers of negative intensities and hence missing values on the log-intensity scale. It avoids missing values in most cases and at the same time dampens down the variability of log-ratios for low intensity spots. See Kooperberg et al (2002) for more details.

`kooperberg` uses the foreground and background intensities, standard deviations and number of pixels to compute empirical estimates of the model parameters as described in equation 2 of Kooperberg et al (2002).

**Value**

An RGList containing the components

R	matrix containing the background adjusted intensities for the red channel for each spot for each array
G	matrix containing the background adjusted intensities for the green channel for each spot for each array
printer	list containing print layout

**Author(s)**

Matthew Ritchie

---

LargeDataObject-class *Large Data Object - class*

---

**Description**

A virtual class including the data classes RGList, MAList and MArrayLM, all of which typically contain large quantities of numerical data in vector, matrices and data.frames.

**Methods**

A show method is defined for objects of class LargeDataObject which uses printHead to print only the leading elements or rows of components or slots which contain large quantities of data.

**Author(s)**

Gordon Smyth

**See Also**

[02.Classes](#) gives an overview of all the classes defined by this package.

## Examples

```
# see normalizeBetweenArrays
```

---

limmaUsersGuide	<i>View Limma User's Guide</i>
-----------------	--------------------------------

---

## Description

Finds the location of the Limma User's Guide and optionally opens it.

## Usage

```
limmaUsersGuide(view=TRUE)
```

## Arguments

`view` logical, should the document be opened using the default PDF document reader?

## Details

The function `vignette("limma")` will find the short limma Vignette which describes how to obtain the Limma User's Guide. The User's Guide is not itself a true vignette because it is not automatically generated using [Sweave](#) during the package build process. This means that it cannot be found using `vignette`, hence the need for this special function.

If the operating system is other than Windows, then the PDF viewer used is that given by `Sys.getenv("R_PDFVIEWER")`. The PDF viewer can be changed using `Sys.putenv(R_PDFVIEWER=)`.

This function is used by drop-down Vignettes menu when the Rgui interface for Windows is used.

## Value

Character string giving the file location.

## Author(s)

Gordon Smyth

## See Also

[vignette](#), [openPDF](#), [openVignette](#), [Sys.getenv](#), [Sys.putenv](#)

## Examples

```
limmaUsersGuide(view=FALSE)
```

lm.series

*Fit Linear Model to Microarray Data by Ordinary Least Squares***Description**

Fit a linear model genewise to expression data from a series of arrays. This function uses ordinary least squares and is a utility function for `lmFit`.

**Usage**

```
lm.series(M, design=NULL, ndups=1, spacing=1, weights=NULL)
```

**Arguments**

M	numeric matrix containing log-ratio or log-expression values for a series of microarrays, rows correspond to genes and columns to arrays
design	numeric design matrix defining the linear model. The number of rows should agree with the number of columns of M. The number of columns will determine the number of coefficients estimated for each gene.
ndups	number of duplicate spots. Each gene is printed ndups times in adjacent spots on each array.
spacing	the spacing between the rows of M corresponding to duplicate spots, spacing=1 for consecutive spots
weights	an optional numeric matrix of the same dimension as M containing weights for each spot. If it is of different dimension to M, it will be filled out to the same size.

**Details**

This is a utility function used by the higher level function `lmFit`. Most users should not use this function directly but should use `lmFit` instead.

The linear model is fit for each gene by calling the function `lm.fit` or `lm.wfit` from the base library.

**Value**

A list with components

coefficients	numeric matrix containing the estimated coefficients for each linear model. Same number of rows as M, same number of columns as design.
stdev.unscaled	numeric matrix conformal with coef containing the unscaled standard deviations for the coefficient estimators. The standard errors are given by <code>stdev.unscaled * sigma</code> .
sigma	numeric vector containing the residual standard deviation for each gene.
df.residual	numeric vector giving the degrees of freedom corresponding to sigma.
qr	QR-decomposition of design

**Author(s)**

Gordon Smyth

**See Also**

[lm.fit](#).

An overview of linear model functions in limma is given by [06.LinearModels](#).

**Examples**

```
# See lmFit for examples
```

---

 lmFit

*Linear Model for Series of Arrays*

---

**Description**

Fit linear model for each gene given a series of arrays

**Usage**

```
lmFit(object, design=NULL, ndups=1, spacing=1, block=NULL, correlation, weights=NULL,
      method="ls", ...)
```

**Arguments**

object	A matrix-like data object containing log-ratios or log-expression values for a series of arrays, with rows corresponding to genes and columns to samples. Any type of data object that can be processed by <a href="#">getEAWP</a> is acceptable.
design	the design matrix of the microarray experiment, with rows corresponding to arrays and columns to coefficients to be estimated. Defaults to the unit vector meaning that the arrays are treated as replicates.
ndups	positive integer giving the number of times each distinct probe is printed on each array.
spacing	positive integer giving the spacing between duplicate occurrences of the same probe, spacing=1 for consecutive rows.
block	vector or factor specifying a blocking variable on the arrays. Has length equal to the number of arrays. Must be NULL if ndups>2.
correlation	the inter-duplicate or inter-technical replicate correlation
weights	non-negative precision weights. Can be a numeric matrix of individual weights of same size as the object expression matrix, or a numeric vector of array weights with length equal to ncol of the expression matrix, or a numeric vector of gene weights with length equal to nrow of the expression matrix.
method	fitting method; "ls" for least squares or "robust" for robust regression
...	other optional arguments to be passed to <code>lm.series</code> , <code>gls.series</code> or <code>mr1m</code>

## Details

This function fits multiple linear models by weighted or generalized least squares. It accepts data from an experiment involving a series of microarrays with the same set of probes. A linear model is fitted to the expression data for each probe. The expression data should be log-ratios for two-color array platforms or log-expression values for one-channel platforms. (To fit linear models to the individual channels of two-color array data, see [lmScFit](#).) The coefficients of the fitted models describe the differences between the RNA sources hybridized to the arrays. The probe-wise fitted model results are stored in a compact form suitable for further processing by other functions in the limma package.

The function allows for missing values and accepts quantitative precision weights through the `weights` argument. It also supports two different correlation structures. If `block` is not NULL then different arrays are assumed to be correlated. If `block` is NULL and `ndups` is greater than one then replicate spots on the same array are assumed to be correlated. It is not possible at this time to fit models with both a block structure and a duplicate-spot correlation structure simultaneously.

If `object` is a matrix then it should contain log-ratios or log-expression data with rows corresponding to probes and columns to arrays. (A numeric vector is treated the same as a matrix with one column.) For objects of other classes, a matrix of expression values is taken from the appropriate component or slot of the object. If `object` is of class `MAList` or `marrayNorm`, then the matrix of log-ratios (M-values) is extracted. If `object` is of class `ExpressionSet`, then the expression matrix is extracted. (This may contain log-expression or log-ratio values, depending on the platform.) If `object` is of class `PLMset` then the matrix of chip coefficients `chip.coefs` is extracted.

The arguments `design`, `ndups`, `spacing` and `weights` will be extracted from the data object if available and do not normally need to be set explicitly in the call. On the other hand, if any of these are set in the function call then they will over-ride the slots or components in the data object. If `object` is an `PLMset`, then weights are computed as  $1/\text{pmax}(\text{object@se.chip.coefs}, 1e-05)^2$ . If `object` is an `ExpressionSet` object, then weights are not computed.

If the argument `block` is used, then it is assumed that `ndups=1`.

The correlation argument has a default value of 0.75, but in normal use this default value should not be relied on and the correlation value should be estimated using the function `duplicateCorrelation`. The default value is likely to be too high in particular if used with the `block` argument.

The actual linear model computations are done by passing the data to one of the lower-level functions `lm.series`, `gls.series` or `mrlm`. The function `mrlm` is used if `method="robust"`. If `method="ls"`, then `gls.series` is used if a correlation structure has been specified, i.e., if `ndups>1` or `block` is non-null and `correlation` is different from zero. If `method="ls"` and there is no correlation structure, `lm.series` is used.

## Value

An `MArrayLM` object containing the result of the fits.

The rownames of `object` are preserved in the fit object and can be retrieved by `rownames(fit)` where `fit` is output from `lmFit`. The column names of `design` are preserved as column names and can be retrieved by `colnames(fit)`.

---

`lmscFit`*Fit Linear Model to Individual Channels of Two-Color Data*

---

**Description**

Fit a linear model to the individual log-intensities for each gene given a series of two-color arrays

**Usage**

```
lmscFit(object, design, correlation)
```

**Arguments**

<code>object</code>	an <code>MAList</code> object or a list from which M and A values may be extracted
<code>design</code>	a numeric matrix containing the design matrix for linear model in terms of the individual channels. The number of rows should be twice the number of arrays. The number of columns will determine the number of coefficients estimated for each gene.
<code>correlation</code>	numeric value giving the intra-spot correlation

**Details**

For two color arrays, the channels measured on the same set of arrays are correlated. The M and A however are uncorrelated for each gene. This function fits a linear model to the set of M and A-values for each gene after re-scaling the M and A-values to have equal variances. The input correlation determines the scaling required. The input correlation is usually estimated using `intraSpotCorrelation` before using `lmscFit`.

Missing values in M or A are not allowed.

**Value**

An object of class `MArrayLM`

## End(Not run)
```

loessFit

*Univariate Lowess With Prior Weights***Description**

Univariate locally weighted linear regression allowing for prior weights. Returns fitted values and residuals.

**Usage**

```
loessFit(y, x, weights=NULL, span=0.3, iterations=4L, min.weight=1e-5, max.weight=1e5,
        equal.weights.as.null=TRUE, method="weightedLowess")
```

**Arguments**

y	numeric vector of response values. Missing values are allowed.
x	numeric vector of predictor values Missing values are allowed.
weights	numeric vector of non-negative prior weights. Missing values are treated as zero.
span	positive numeric value between 0 and 1 specifying proportion of data to be used in the local regression moving window. Larger numbers give smoother fits.
iterations	number of local regression fits. Values greater than 1 produce robust fits.
min.weight	minimum weight. Any lower weights will be reset.
max.weight	maximum weight. Any higher weights will be reset.
equal.weights.as.null	should equal weights be treated as if weights were NULL, so that lowess is called? Applies even if all weights are all zero.
method	method used for weighted lowess. Possibilities are "weightedLowess", "loess" or "locfit".

## Details

This function is essentially a wrapper function for `lowess` and `weightedLowess` with added error checking. The idea is to provide the classic univariate lowess algorithm of Cleveland (1979) but allowing for prior weights and missing values.

The venerable `lowess` code is fast, uses little memory and has an accurate interpolation scheme, so it is an advantage to use it when prior weights are not needed. This function calls `lowess` when `weights=NULL`, but returns values in original rather than sorted order and allows missing values. The treatment of missing values is analogous to `na.exclude`.

By default, weights that are all equal (even all zero) are treated as if they were `NULL`, so `lowess` is called in this case also.

When unequal weights are provided, this function calls `weightedLowess` by default, although two other possibilities are also provided. `weightedLowess` implements a similar algorithm to `lowess` except that it uses the prior weights both in the local regressions and in determining which other observations to include in the local neighbourhood of each observation.

Two alternative algorithms for weighted lowess curve fitting are provided as options. If `method="loess"`, then a call is made to `loess(y~x, weights=weights, span=span, degree=1, family="symmetric", ...)`. This method differs from `weightedLowess` in that the prior weights are ignored when determining the neighbourhood of each observation.

If `method="locfit"`, then repeated calls are made to `locfit:::locfit.raw` with `deg=1`. In principle, this is similar to "loess", but "locfit" makes some approximations and is very much faster and uses much less memory than "loess" for long data vectors.

The arguments `span` and `iterations` here have the same meaning as for `weightedLowess` and `loess`. `span` is equivalent to the argument `f` of `lowess` while `iterations` is equivalent to `iter+1` for `lowess`. It gives the total number of fits rather than the number of robustifying fits.

When there are insufficient observations to estimate the loess curve, `loessFit` returns a linear regression fit. This mimics the behavior of `lowess` but not that of `loess` or `locfit.raw`.

## Value

A list with components

<code>fitted</code>	numeric vector of same length as <code>y</code> giving the loess fit
<code>residuals</code>	numeric vector of same length as <code>x</code> giving residuals from the fit

## Note

With unequal weights, "loess" was the default method prior to `limma` version 3.17.25. The default was changed to "locfit" in `limma` 3.17.25, and then to "weightedLowess" in `limma` 3.19.16. "weightedLowess" will potentially give somewhat different results to the older algorithms because the local neighbourhood of each observation is determined differently (more carefully).

If `weights=NULL`, this function calls `lowess`. Otherwise it calls `weightedLowess`, `locfit.raw` or `loess`. See the help pages of those functions for references and credits.

Compare with `loess` in the stats package.

See [05.Normalization](#) for an outline of the limma package normalization functions.

**Examples**

```
x <- (1:100)/101
y <- sin(2*pi*x)+rnorm(100,sd=0.4)
out <- loessFit(y,x)
plot(x,y)
lines(x,out$fitted,col="red")

# Example using weights

y <- x-0.5
w <- rep(c(0,1),50)
y[w==0] <- rnorm(50,sd=0.1)
pch <- ifelse(w>0,16,1)
plot(x,y,pch=pch)
out <- loessFit(y,x,weights=w)
lines(x,out$fitted,col="red")
```

---

logcosh

*Logarithm of cosh*

---

**Description**

Compute  $\log(\cosh(x))$  without floating overflow or underflow

**Usage**

```
logcosh(x)
```

**Arguments**

`x` a numeric vector or matrix.

**Details**

The computation uses asymptotic expressions for very large or very small arguments. For intermediate arguments,  $\log(\cosh(x))$  is returned.

**Value**

Numeric vector or matrix of same dimensions as `x`.

**Author(s)**

Gordon K Smyth

**See Also**[logsumexp](#)**Examples**

```
x <- c(1e-8, 1e-7, 1e-6, 1e-5, 1e-4, 1, 3, 50, 800)
logcosh(x)
log(cosh(x))
```

---

`logsumexp`*Log Sum of Exponentials*

---

**Description**

Compute  $\log(\exp(x) + \exp(y))$  without floating overflow or underflow

**Usage**

```
logsumexp(x, y)
```

**Arguments**

`x` a numeric vector or matrix.  
`y` a numeric vector or matrix of same size as `x`.

**Details**

The computation uses `logcosh()`.

**Value**

Numeric vector or matrix of same dimensions as `x`.

**Author(s)**

Gordon K Smyth

**See Also**[logcosh](#)**Examples**

```
x <- y <- c(1e-8, 1e-7, 1e-6, 1e-5, 1e-4, 1, 3, 50, 800)
logsumexp(x, y)
log( exp(x)+exp(y) )
```

---

`ma3x3`*Two dimensional Moving Averages with 3x3 Window*

---

### Description

Apply a specified function to each to each value of a matrix and its immediate neighbors.

### Usage

```
ma3x3.matrix(x,FUN=mean,na.rm=TRUE,...)
ma3x3.spottedarray(x,printer,FUN=mean,na.rm=TRUE,...)
```

### Arguments

<code>x</code>	numeric matrix
<code>FUN</code>	function to apply to each window of values
<code>na.rm</code>	logical value, should missing values be removed when applying FUN
<code>...</code>	other arguments are passed to FUN
<code>printer</code>	list giving the printer layout, see <a href="#">PrintLayout-class</a>

### Details

For `ma3x3.matrix`, `x` is an arbitrary function. for `ma3x3.spotted`, each column of `x` is assumed to contain the expression values of a spotted array in standard order. The printer layout information is used to re-arrange the values of each column as a spatial matrix before applying `ma3x3.matrix`.

### Value

Numeric matrix of same dimension as `x` containing smoothed values

### Author(s)

Gordon Smyth

### See Also

An overview of functions for background correction are given in [04.Background](#).

### Examples

```
x <- matrix(c(2,5,3,1,6,3,10,12,4,6,4,8,2,1,9,0),4,4)
ma3x3.matrix(x,FUN="mean")
ma3x3.matrix(x,FUN="min")
```

---

makeContrasts	<i>Construct Matrix of Custom Contrasts</i>
---------------	---

---

### Description

Construct the contrast matrix corresponding to specified contrasts of a set of parameters.

### Usage

```
makeContrasts(..., contrasts=NULL, levels)
```

### Arguments

...	expressions, or character strings which can be parsed to expressions, specifying contrasts
contrasts	character vector specifying contrasts
levels	character vector or factor giving the names of the parameters of which contrasts are desired, or a design matrix or other object with the parameter names as column names.

### Details

This function expresses contrasts between a set of parameters as a numeric matrix. The parameters are usually the coefficients from a linear model fit, so the matrix specifies which comparisons between the coefficients are to be extracted from the fit. The output from this function is usually used as input to `contrasts.fit`. The contrasts can be specified either as expressions using ... or as a character vector through contrasts. (Trying to specify contrasts both ways will cause an error.)

The parameter names must be syntactically valid variable names in R and so, for example, must begin with a letter rather than a numeral. See `make.names` for a complete specification of what is a valid name.

### Value

Matrix which columns corresponding to contrasts.

### Author(s)

Gordon Smyth

### See Also

An overview of linear model functions in limma is given by the help page [06.LinearModels](#).

### Examples

```
makeContrasts(B-A,C-B,C-A,levels=c("A","B","C"))
makeContrasts(contrasts="A-(B+C)/2",levels=c("A","B","C"))
x <- c("B-A","C-B","C-A")
makeContrasts(contrasts=x,levels=c("A","B","C"))
```

---

makeUnique	<i>Make Values of Character Vector Unique</i>
------------	---

---

**Description**

Paste characters on to values of a character vector to make them unique.

**Usage**

```
makeUnique(x)
```

**Arguments**

x                      object to be coerced to a character vector

**Details**

Repeat values of x are labelled with suffixes "1", "2" etc.

**Value**

A character vector of the same length as x

**Author(s)**

Gordon Smyth

**See Also**

makeUnique is called by [merge.RGList](#). Compare with [make.unique](#) in the base package.

**Examples**

```
x <- c("a", "a", "b")
makeUnique(x)
```

---

MAList-class	<i>M-value, A-value Expression List - class</i>
--------------	---

---

**Description**

A simple list-based class for storing M-values and A-values for a batch of spotted microarrays. MAList objects are usually created during normalization by the functions [normalizeWithinArrays](#) or [MA.RG](#).

**Slots/List Components**

MAList objects can be created by `new("MAList", MA)` where MA is a list. This class contains no slots (other than `.Data`), but objects should contain the following components:

- M: numeric matrix containing the M-values (log-2 expression ratios). Rows correspond to spots and columns to arrays.
- A: numeric matrix containing the A-values (average log-2 expression values).

Optional components include:

- weights: numeric matrix of same dimensions as M containing relative spot quality weights. Elements should be non-negative.
- other: list containing other matrices, all of the same dimensions as M.
- genes: data.frame containing probe information. Should have one row for each spot. May have any number of columns.
- targets: data.frame containing information on the target RNA samples. Rows correspond to arrays. May have any number of columns.
- printer: list containing information on the process used to print the spots on the arrays. See [PrintLayout](#).

Valid MAList objects may contain other optional components, but all probe or array information should be contained in the above components.

## Methods

This class inherits directly from class `list` so any operation appropriate for lists will work on objects of this class. In addition, MAList objects can be [subsetting](#) and [combined](#). RGList objects will return dimensions and hence functions such as `dim`, `nrow` and `ncol` are defined. MALists also inherit a `show` method from the virtual class `LargeDataObject`, which means that RGLists will print in a compact way.

Other functions in LIMMA which operate on MAList objects include [normalizeWithinArrays](#), [normalizeBetweenArrays](#), [normalizeForPrintorder](#), [plotMA](#) and [plotPrintTipLoess](#).

## Author(s)

Gordon Smyth

## See Also

- [02.Classes](#) gives an overview of all the classes defined by this package.
- `marrayNorm` is the corresponding class in the `marray` package.

---

MArrayLM-class

*Microarray Linear Model Fit - class*

---

## Description

A list-based S4 class for storing the results of fitting gene-wise linear models to a set of microarrays. Objects are normally created by [lmFit](#), and additional components are added by [eBayes](#).

## Components

MArrayLM objects do not contain any slots (apart from `.Data`) but they should contain the following list components:

- `coefficients` matrix containing fitted coefficients or contrasts
- `stdev.unscaled` matrix containing unscaled standard deviations of the coefficients or contrasts
- `sigma` numeric vector containing residual standard deviations for each gene
- `df.residual` numeric vector containing residual degrees of freedom for each gene

The following additional components may be created by `lmFit`:

- `Amean` numeric vector containing the average log-intensity for each probe over all the arrays in the original

genes	data.frame containing probe annotation.
design	design matrix.
cov.coefficients	numeric matrix giving the unscaled covariance matrix of the estimable coefficients
pivot	integer vector giving the order of coefficients in cov.coefficients. Is computed by the QR-decomposition of the design matrix (if the fit involved no weights or missing values).
qr	QR-decomposition of the design matrix (if the fit involved no weights or missing values).
...	other components returned by <code>lm.fit</code> (if the fit involved no weights or missing values).

The following component may be added by `contrasts.fit`:

`contrasts` numeric matrix defining contrasts of coefficients for which results are desired.

The following components may be added by `eBayes`:

<code>s2.prior</code>	numeric value giving empirical Bayes estimated prior value for residual variances
<code>df.prior</code>	numeric vector giving empirical Bayes estimated degrees of freedom associated with <code>s2.prior</code> for each gene
<code>df.total</code>	numeric vector giving total degrees of freedom used for each gene, usually equal to <code>df.prior + df.residual</code>
<code>s2.post</code>	numeric vector giving posterior residual variances
<code>var.prior</code>	numeric vector giving empirical Bayes estimated prior variance for each true coefficient
<code>F</code>	numeric vector giving moderated F-statistics for testing all contrasts equal to zero
<code>F.p.value</code>	numeric vector giving p-value corresponding to <code>F.stat</code>
<code>t</code>	numeric matrix containing empirical Bayes t-statistics

## Methods

MArrayLM objects will return dimensions and hence functions such as `dim`, `nrow` and `ncol` are defined. MArrayLM objects inherit a `show` method from the virtual class `LargeDataObject`.

The functions `eBayes`, `decideTests` and `classifyTestsF` accept MArrayLM objects as arguments.

## Author(s)

Gordon Smyth

[02.Classes](#) gives an overview of all the classes defined by this package.

---

mdplot

*Mean-Difference Plot*

---

## Description

Creates a mean-difference plot of two columns of a matrix.

## Usage

```
mdplot(x, columns=c(1,2), xlab="Mean", ylab="Difference", main=NULL, ...)
```

**Arguments**

x	numeric matrix with at least two columns.
columns	which columns of x to compare. Plot will display second minus first.
xlab	label for the x-axis.
ylab	label for the y-axis.
main	title of the plot. Defaults to
...	any other arguments are passed to <a href="#">plotWithHighlights</a> .

**Details**

Plots differences vs means for a set of bivariate values. This is a generally useful approach for comparing two correlated measures of the same underlying phenomenon. Bland and Altman (1986) argue it is more information than a simple scatterplot of the two variables. The bivariate values are stored as columns of x.

**Value**

A plot is created on the current graphics device.

**Author(s)**

Gordon Smyth

[plotMD](#) is an object-oriented implementation of mean-difference plots for expression data.

An overview of diagnostic functions available in LIMMA is given in [09.Diagnostics](#).

**Examples**

```
x1 <- runif(100)
x2 <- (x1 + rnorm(100, sd=0.01))^1.2
oldpar <- par(mfrow=c(1,2))
plot(x1, x2)
mdplot(cbind(x1, x2), bg.pch=1, bg.cex=1)
par(oldpar)
```

---

merge

*Merge RGList or MAList Data Objects*

---

### Description

Merge two microarray data sets represented by RGLists in possibly irregular order.

### Usage

```
## S3 method for class 'RGList'  
merge(x,y,...)
```

### Arguments

x	data object of class <a href="#">RGList</a> , <a href="#">MAList</a> , <a href="#">EList</a> or <a href="#">EListRaw</a> .
y	data object of same class as x, corresponding to the same genes as for x, possibly in a different order, but with different arrays.
...	other arguments are accepted but not used at present

### Details

RGList, MAList, EListRaw and EList data objects are lists containing numeric matrices all of the same dimensions. The data objects are merged by merging each of the components by row names or, if there are no row names, by IDs in the genes component. Unlike when using [cbind](#), row names are not required to be in the same order or to be unique. In the case of repeated row names, the order of the rows with repeated names is preserved. This means that the first occurrence of each name in x is matched with the first occurrence of the same name in y, the second with the second, and so on. The final vector of row names is the same as in x.

Note: if the objects contain the same number of genes in the same order then the appropriate function to combine them is [cbind](#) rather than merge.

### Value

An merged object of the same class as x and y with the same components as x. Component matrices have the same rows names as in x but columns from y as well as from x.

### Author(s)

Gordon Smyth

### See Also

R base provides a [merge](#) method for merging data.frames.

An overview of limma commands for reading, subsetting and merging data is given in [03.Reading-Data](#).

**Examples**

```

M <- A <- matrix(11:14,4,2)
rownames(M) <- rownames(A) <- c("a","a","b","c")
MA1 <- new("MAList",list(M=M,A=A))

M <- A <- matrix(21:24,4,2)
rownames(M) <- rownames(A) <- c("b","a","a","c")
MA2 <- new("MAList",list(M=M,A=A))

merge(MA1,MA2)
merge(MA2,MA1)

```

mergeScans

*Merge two scans of two-color arrays***Description**

Merge two sets of intensities of two-color arrays that are scanned twice at two different scanner settings, one at a lower gain setting with no saturated spot intensities and the other at a higher gain setting with a higher signal-to-noise ratio and some saturated spot intensities.

**Usage**

```
mergeScansRG(RGlow, RGhigh, AboveNoiseLowG=NULL, AboveNoiseLowR=NULL, outlierp=0.01)
```

**Arguments**

RGlow	object of class RGList containing red and green intensities constituting two-color microarray data scanned at a lower gain setting.
RGhigh	object of class RGList containing red and green intensities constituting two-color microarray data scanned at a higher gain setting.
AboveNoiseLowG	matrix of 1 or 0 for low scan intensities of green color, 1 for spots above noise level or 0 otherwise. One column per array.
AboveNoiseLowR	matrix of 1 or 0 for low scan intensities of red color, 1 for spots above noise level or 0 otherwise. One column per array.
outlierp	p-value for outliers. 0 for no outlier detection or any value between 0 and 1. Default p-value is 0.01.

**Details**

This function merges two separate scans of each fluorescent label on a two-color array scanned at two different scanner settings by using a nonlinear regression model consisting of two linear regression lines and a quadratic function connecting the two, which looks like a hockey stick. The changing point, i.e. the saturation point, in high scan is also estimated as part of model. Signals produced for certain spots can sometimes be very low (below noise) or too high (saturated) to be accurately read by the scanner. The proportions of spots that are below noise or above saturation are affected by the settings of the laser scanner used to read the arrays, with low scans minimizing saturation effects and high scans maximizing signal-to-noise ratios. Saturated spots can cause bias in intensity ratios that cannot be corrected for using conventional normalization methods.

Each fluorescent label on a two-color array can be scanned twice: for example, a high scan targeted at reaching saturation level for the brightest 1 percent of the spots on the array, and a low scan targeted at the lowest level of intensity which still allowed accurate grid placement on the arrays. By merging data from two separate laser scans of each fluorescent label on an array, we can avoid the potential bias in signal intensities due to below noise or above saturation and, thus provide better estimates of true differential expression as well as increase usable spots.

The merging process is designed to retain signal intensities from the high scan except when scanner saturation causes the high scan signal to be under-measured. The saturated spots are predicted from the corresponding low scans by the fitted regression model. It also checks any inconsistency between low and high scans.

### Value

An object of class `RGList-class` with the following components:

G	numeric matrix containing the merged green (cy3) foreground intensities. Rows correspond to spots and columns to arrays.
R	numeric matrix containing the merged red (cy5) foreground intensities. Rows correspond to spots and columns to arrays.
Gb	numeric matrix containing the green (cy3) background intensities from high scan.
Rb	numeric matrix containing the red (cy5) background intensities from high scan.
other	list numeric matrices <code>Gsaturated</code> , <code>Rsaturated</code> , <code>Goutlier</code> and <code>Routlier</code> . The first two contain saturation flags (1=saturated, 0=otherwise) for the green (cy3) and red (Cy5) channels of the high scan. The second two contain outlier flags (1=outlier, 0=otherwise) for the green (cy3) and red (Cy5) channels.

`modelMatrix`*Construct Design Matrix*

---

**Description**

Construct design matrix from RNA target information for a two colour microarray experiment.

**Usage**

```
modelMatrix(targets, parameters, ref, verbose=TRUE)
uniqueTargets(targets)
```

**Arguments**

<code>targets</code>	matrix or data.frame with columns Cy3 and Cy5 specifying which RNA was hybridized to each array
<code>parameters</code>	matrix specifying contrasts between RNA samples which should correspond to regression coefficients. Row names should correspond to unique RNA sample names found in <code>targets</code> .
<code>ref</code>	character string giving name of one of the RNA sources to be treated as reference. Exactly one argument of <code>parameters</code> or <code>ref</code> should be specified.
<code>verbose</code>	logical, if TRUE then unique names found in <code>targets</code> will be printed to standard output

**Details**

This function computes a design matrix for input to `lmFit` when analysing two-color microarray experiments in terms of log-ratios.

If the argument `ref` is used, then the experiment is treated as a one-way layout and the coefficients measure expression changes relative to the RNA source specified by `ref`. The RNA source `ref` is often a common reference which appears on every array or is a control sample to which all the others are compared. There is no restriction however. One can choose `ref` to be any of the RNA sources appearing the Cy3 or Cy5 columns of `targets`.

If the `parameters` argument is set, then the columns of this matrix specify the comparisons between the RNA sources which are of interest. This matrix must be of size  $n$  by  $(n-1)$ , where  $n$  is the number of unique RNA sources found in Cy3 and Cy5, and must have row names which correspond to the RNA sources.

**Value**

`modelMatrix` produces a numeric design matrix with row names as in `targets` and column names as in `parameters`.

`uniqueTargets` produces a character vector of unique target names from the columns Cy3 and Cy5 of `targets`.

`model.matrix` in the stats package.

An overview of linear model functions in limma is given by [06.LinearModels](#).

**Examples**

```
targets <- cbind(Cy3=c("Ref", "Control", "Ref", "Treatment"), Cy5=c("Control", "Ref", "Treatment", "Ref"))
rownames(targets) <- paste("Array", 1:4)
```

```
parameters <- cbind(C=c(-1, 1, 0), T=c(-1, 0, 1))
rownames(parameters) <- c("Ref", "Control", "Treatment")
```

```
modelMatrix(targets, parameters)
modelMatrix(targets, ref="Ref")
```

---

modifyWeights

*Modify Matrix of Weights By Control Status of Rows*

---

**Description**

Modify weights matrix for given gene status values.

**Usage**

```
modifyWeights(weights=rep(1, length(status)), status, values, multipliers)
```

**Arguments**

weights	numeric matrix of relative weights, rows corresponding to genes and columns to arrays
status	character vector giving the control status of each spot on the array, of same length as the number of rows of weights
values	character vector giving subset of the unique values of status
multipliers	numeric vector of same length as values giving factor by which weights will be modified

**Details**

The function is usually used to temporarily modify the weights matrix during normalization of data. The function can be used for example to give zero weight to spike-in ratio control spots during normalization.

**Value**

Numeric matrix of same dimensions as weights with rows corresponding to values in status modified by the specified multipliers.

**Author(s)**

Gordon Smyth

**See Also**

An overview of normalization functions available in LIMMA is given in [05.Normalization](#).

**Examples**

```
w <- matrix(runif(6*3),6,3)
status <- c("Gene","Gene","Ratio_Control","Ratio_Control","Gene","Gene")
modifyWeights(w,status,values="Ratio_Control",multipliers=0)
```

---

mrlm

*Fit Linear Model to Microarray Data by Robust Regression*

---

**Description**

Fit a linear model genewise to expression data from a series of arrays. The fit is by robust M-estimation allowing for a small proportion of outliers. This is a utility function for `lmFit`.

**Usage**

```
mrlm(M,design=NULL,ndups=1,spacing=1,weights=NULL,...)
```

**Arguments**

M	numeric matrix containing log-ratio or log-expression values for a series of microarrays, rows correspond to genes and columns to arrays.
design	numeric design matrix defining the linear model, with rows corresponding to arrays and columns to comparisons to be estimated. The number of rows must match the number of columns of M. Defaults to the unit vector meaning that the arrays are treated as replicates.
ndups	a positive integer giving the number of times each gene is printed on an array. <code>nrow(M)</code> must be divisible by <code>ndups</code> .
spacing	the spacing between the rows of M corresponding to duplicate spots, <code>spacing=1</code> for consecutive spots.
weights	numeric matrix of the same dimension as M containing weights. If it is of different dimension to M, it will be filled out to the same size. NULL is equivalent to equal weights.
...	any other arguments are passed to <code>r1m.default</code> .

**Details**

This is a utility function used by the higher level function `lmFit`. Most users should not use this function directly but should use `lmFit` instead.

This function fits a linear model for each gene by calling the function `r1m` from the MASS library.

Warning: don't use weights with this function unless you understand how `r1m` treats weights. The treatment of weights is somewhat different from that of `lm.series` and `gls.series`.

**Value**

A list with components

coefficients	numeric matrix containing the estimated coefficients for each linear model. Same number of rows as M, same number of columns as design.
stdev.unscaled	numeric matrix conformal with coef containing the unscaled standard deviations for the coefficient estimators. The standard errors are given by <code>stdev.unscaled * sigma</code> .
sigma	numeric vector containing the residual standard deviation for each gene.
df.residual	numeric vector giving the degrees of freedom corresponding to sigma.
qr	QR decomposition of design.

nec	<i>NormExp Background Correction and Normalization Using Control Probes</i>
-----	---

---

**Description**

Perform normexp background correction using negative control probes and quantile normalization using negative and positive control probes. Particularly useful for Illumina BeadChips.

**Usage**

```
nec(x, status=NULL, negctrl="negative", regular="regular", offset=16,
    robust=FALSE, detection.p="Detection")
neqc(x, status=NULL, negctrl="negative", regular="regular", offset=16,
     robust=FALSE, detection.p="Detection", ...)
```

**Arguments**

x	object of class <code>EListRaw</code> or <code>matrix</code> containing raw intensities for regular and control probes from a series of microarrays.
status	character vector giving probe types. Defaults to <code>x\$genes\$Status</code> if <code>x</code> is an <code>EListRaw</code> object.
negctrl	character string identifier for negative control probes.
regular	character string identifier for regular probes, i.e., all probes other than control probes.
offset	numeric value added to the intensities after background correction.
robust	logical. Should robust estimators be used for the background mean and standard deviation?

detection.p      detection p-values. Only used when no negative control probes can be found in the data. Can be a numeric matrix or a character string giving the name of the component of `x$other` containing the matrix.

...                any other arguments are passed to `normalizeBetweenArrays`.

## Details

`nec` performs background correction followed by quantile normalization, using negative control probes for background correction and both negative and positive controls for normalization (Shi et al, 2010). `nec` is similar but performs background correction only. These methods are particularly designed for Illumina BeadChip microarrays, but could be useful for other platforms for which good quality negative control probes or detection p-values are available.

When control data are available, these function call `normexp.fit.control` to estimate the parameters required by `normal+exponential(normexp)` convolution model with the help of negative control probes, followed by `normexp.signal` to perform the background correction. If `x` contains background intensities `x$Eb`, then these are first subtracted from the foreground intensities, prior to `normexp` background correction. After background correction, an `offset` is added to the data.

When expression values for negative controls are not available, the `detection.p` argument is used instead. In that case, these functions call `normexp.fit.detection.p`, which infers the negative control probe intensities from the detection p-values associated with the regular probes. The function outputs a message if this is done.

For more detailed descriptions of the arguments `x`, `status`, `negctrl`, `regular` and `detection.p`, please refer to functions `normexp.fit.control`, `normexp.fit.detection.p` and `read.ilmn`.

Both `nec` and `necq` perform the above steps. `necq` continues on to quantile normalize the background-corrected intensities, including control probes. After normalization, the intensities are `log2` transformed and the control probes are removed.

## Value

`nec` produces a `EListRaw-class` or matrix object of the same dimensions as `x` containing background-corrected intensities, on the raw scale. `necq` produces a `EList-class` or matrix object containing normalized `log2` intensities, with rows corresponding to control probes removed.

`normexp.fit.control` estimates the parameters in the `normal+exponential` convolution model using the negative control probes.

`normexp.fit.detection.p` estimates the parameters in the normal+exponential convolution model using negative control probe intensities inferred from regular probes by using their detection p values information.

`normexp.fit` estimates parameters in the normal+exponential convolution model using a saddle-point approximation or other methods.

`neqc` performs normexp background correction and quantile normalization aided by control probes.

## Examples

```
## Not run:
# neqc normalization for data which include control probes
x <- read.ilmn(files="sample probe profile.txt", ctrlfiles="control probe profile.txt")
y <- neqc(x)
fit <- lmFit(y,design)

# Same thing but in separate steps:
x.b <- nec(x)
y <- normalizeBetweenArrays(x.b,method="quantile")
y <- y[y$genes$Status=="regular",]

# neqc normalization for data without control probes
# neqc can process detection p-values in lieu of control probes
xr <- read.ilmn(files="sample probe profile.txt")
yr <- neqc(xr)

## End(Not run)
```

---

normalizeBetweenArrays

*Normalize Between Arrays*

---

## Description

Normalizes expression intensities so that the intensities or log-ratios have similar distributions across a set of arrays.

## Usage

```
normalizeBetweenArrays(object, method=NULL, targets=NULL, cyclic.method="fast", ...)
```

## Arguments

object	a numeric matrix, <code>EListRaw</code> , <code>RGList</code> or <code>MAList</code> object containing un-normalized expression data. If a matrix, then it is assumed to contain log-transformed single-channel data.
method	character string specifying the normalization method to be used. Choices for single-channel data are "none", "scale", "quantile" or "cyclicloess". Choices for two-color data are those previously mentioned plus "Aquantile", "Gquantile", "Rquantile" or "Tquantile". A partial string sufficient to uniquely identify the choice is permitted. The default is "Aquantile" for two-color data objects or "quantile" for single-channel objects.

targets	vector, factor or matrix of length twice the number of arrays, used to indicate target groups if method="Tquantile"
cyclic.method	character string indicating the variant of normalizeCyclicLoess to be used if method="cyclicloess", see <a href="#">normalizeCyclicLoess</a> for possible values.
...	other arguments are passed to normalizeQuantiles or normalizeCyclicLoess

## Details

normalizeBetweenArrays normalizes expression values to achieve consistency between arrays. For two-color arrays, normalization between arrays is usually a follow-up step after normalization within arrays using normalizeWithinArrays. For single-channel arrays, within array normalization is not usually relevant and so normalizeBetweenArrays is the sole normalization step.

For single-channel data, the scale, quantile or cyclic loess normalization methods can be applied to the columns of data. Trying to apply other normalization methods when object is a matrix or EListRaw object will produce an error. If object is an EListRaw object, then normalization will be applied to the matrix object\$E of expression values, which will then be log2-transformed. Scale (method="scale") scales the columns to have the same median. Quantile and cyclic loess normalization was originally proposed by Bolstad et al (2003) for Affymetrix-style single-channel arrays. Quantile normalization forces the entire empirical distribution of each column to be identical. Cyclic loess normalization applies loess normalization to all possible pairs of arrays, usually cycling through all pairs several times. Cyclic loess is slower than quantile, but allows probe-wise weights and is more robust to unbalanced differential expression.

The other normalization methods are for two-color arrays. Scale normalization was proposed by Yang et al (2001, 2002) and is further explained by Smyth and Speed (2003). The idea is simply to scale the log-ratios to have the same median-absolute-deviation (MAD) across arrays. This idea has also been implemented by the maNormScale function in the marray package. The implementation here is slightly different in that the MAD scale estimator is replaced with the median-absolute-value and the A-values are normalized as well as the M-values.

Quantile normalization was explored by Yang and Thorne (2003) for two-color cDNA arrays. method="quantile" ensures that the intensities have the same empirical distribution across arrays and across channels. method="Aquantile" ensures that the A-values (average intensities) have the same empirical distribution across arrays leaving the M-values (log-ratios) unchanged. These two methods are called "q" and "Aq" respectively in Yang and Thorne (2003).

method="Tquantile" performs quantile normalization separately for the groups indicated by targets. targets may be a target frame such as read by readTargets or can be a vector indicating green channel groups followed by red channel groups.

method="Gquantile" ensures that the green (first) channel has the same empirical distribution across arrays, leaving the M-values (log-ratios) unchanged. This method might be used when the green channel is a common reference throughout the experiment. In such a case the green channel represents the same target throughout, so it makes compelling sense to force the distribution of intensities to be same for the green channel on all the arrays, and to adjust to the red channel accordingly. method="Rquantile" ensures that the red (second) channel has the same empirical distribution across arrays, leaving the M-values (log-ratios) unchanged. Both Gquantile and Rquantile normalization have the implicit effect of changing the red and green log-intensities by equal amounts.

See the limma User's Guide for more examples of use of this function.

## Value

If object is a matrix then normalizeBetweenArrays produces a matrix of the same size. If object is an EListRaw object, then an EList object with expression values on the log2 scale is produced.

For two-color data, `normalizeBetweenArrays` produces an `MAList` object with M and A-values on the log<sub>2</sub> scale.

```
ngenes <- 100
narrays <- 4
x <- matrix(rnorm(ngenes*narrays),100,4)
y <- normalizeBetweenArrays(x)
```

---

`normalizeCyclicLoess` *Normalize Columns of a Matrix by Cyclic Loess*

---

### Description

Normalize the columns of a matrix, cyclicly applying loess normalization to normalize each pair of columns to each other.

**Usage**

```
normalizeCyclicLoess(x, weights = NULL, span=0.7, iterations = 3, method = "fast")
```

**Arguments**

x	numeric matrix, or object which can be coerced to a numeric matrix, containing log-expression values.
weights	numeric vector of probe weights. Must be non-negative.
span	span of loess smoothing window, between 0 and 1.
iterations	number of times to cycle through all pairs of columns.
method	character string specifying which variant of the cyclic loess method to use. Options are "fast", "affy" or "pairs".

**Details**

This function is intended to normalize single channel or A-value microarray intensities between arrays. Cyclic loess normalization is similar effect and intention to quantile normalization, but with some advantages, in particular the ability to incorporate probe weights.

A number of variants of cyclic loess have been suggested. `method="pairs"` implements the intuitive idea that each pair of arrays is subjected to loess normalization as for two-color arrays. This process is simply cycled through all possible pairs of arrays, then repeated for several iterations. This is the method described by Ballman et al (2004) as ordinary cyclic loess normalization.

`method="affy"` implements a method similar to `normalize.loess` in the `affy` package, except that here we call `lowess` instead of `loess` and avoid the use of probe subsets and the `predict` function. In this approach, no array is modified until a complete cycle of all pairs has been completed. The adjustments are stored for a complete iteration, then averaged, and finally used to modify the arrays. The "affy" method is invariant to the order of the columns of `x`, whereas the "pairs" method is not. The affy approach is presumably that used by Bolstad et al (2003), although the algorithm was not explicitly described in that article.

`method="fast"` implements the "fast linear loess" method of Ballman et al (2004), whereby each array is simply normalized to a reference array, the reference array being the average of all the arrays. This method is relatively fast because computational time is linear in the number of arrays, whereas "pairs" and "affy" are quadratic in the number of arrays. "fast" requires  $n$  lowess fits per iteration, where  $n$  is the number of arrays, whereas "pairs" and "affy" require  $n*(n-1)/2$  lowess fits per iteration.

**Value**

A matrix of the same dimensions as `x` containing the normalized values.

[normalize.loess](#) in the affy package also implements cyclic loess normalization, without weights.

---

normalizeForPrintorder

*Print-Order Normalization*

---

**Description**

Normalize intensity values on one or more spotted microarrays to adjust for print-order effects.

**Usage**

```
normalizeForPrintorder(object, layout, start="topleft", method = "loess",
                      separate.channels = FALSE, span = 0.1, plate.size = 32)
normalizeForPrintorder.rg(R, G, printorder, method = "loess", separate.channels = FALSE,
                        span = 0.1, plate.size = 32, plot = FALSE)
plotPrintorder(object, layout, start="topleft", slide = 1, method = "loess",
               separate.channels = FALSE, span = 0.1, plate.size = 32)
```

**Arguments**

object	an RGList or list object containing components R and G which are matrices containing the red and green channel intensities for a series of arrays
R	numeric vector containing red channel intensities for a single microarray
G	numeric vector containing the green channel intensities for a single microarray
layout	list specifying the printer layout, see <a href="#">PrintLayout-class</a>
start	character string specifying where printing starts in each pin group. Choices are "topleft" or "topright".
printorder	numeric vector specifying order in which spots are printed. Can be computed from <code>printorder(layout, start=start)</code> .
slide	positive integer giving the column number of the array for which a plot is required
method	character string, "loess" if a smooth loess curve should be fitted through the print-order trend or "plate" if plate effects are to be estimated
separate.channels	logical, TRUE if normalization should be done separately for the red and green channel and FALSE if the normalization should be proportional for the two channels
span	numerical constant between 0 and 1 giving the smoothing span for the loess curve. Ignored if method="plate".
plate.size	positive integer giving the number of consecutive spots corresponding to one plate or plate pack. Ignored if method="loess".
plot	logical. If TRUE then a scatter plot of the print order effect is sent to the current graphics device.

## Details

Print-order is associated with the 384-well plates used in the printing of spotted microarrays. There may be variations in DNA concentration or quality between the different plates. There may be variations in ambient conditions during the time the array is printed.

This function is intended to pre-process the intensities before other normalization methods are applied to adjust for variations in DNA quality or concentration and other print-order effects.

Printorder means the order in which spots are printed on a microarray. Spotted arrays are printed using a print head with an array of print-tips. Spots in the various tip-groups are printed in parallel. Printing is assumed to start in the top left hand corner of each tip-groups and to proceed right and down by rows, or else to start in the top right hand and to proceed left and down by rows. See [printorder](#) for more details. (WARNING: this is not always the case.) This is true for microarrays printed at the Australian Genome Research Facility but might not be true for arrays from other sources.

If object is an RGList then printorder is performed for each intensity in each array.

plotPrintorder is a non-generic function which calls normalizeForPrintorder with plot=TRUE.

## Value

normalizeForPrintorder produces an RGList containing normalized intensities.

The function plotPrintorder or normalizeForPrintorder.rg with plot=TRUE returns no value but produces a plot as a side-effect.

normalizeForPrintorder.rg with plot=FALSE returns a list with the following components:

R	numeric vector containing the normalized red channel intensities
G	numeric vector containing the normalized green channel intensities
R.trend	numeric vector containing the fitted printorder trend for the red channel
G.trend	numeric vector containing the fitted printorder trend for the green channel

---

`normalizeMedianAbsValues`*Normalize Columns of a Matrix to have the Median Absolute Value*

---

### Description

Performs scale normalization of an M-value matrix or an A-value matrix across a series of arrays. Users do not normally need to call these functions directly - use `normalizeBetweenArrays` instead.

### Usage

```
normalizeMedianValues(x)
normalizeMedianAbsValues(x)
```

### Arguments

`x` numeric matrix

### Details

If `x` is a matrix of log-ratios of expression (M-values) then `normalizeMedianAbsValues` is very similar to scaling to equalize the median absolute deviation (MAD) as in Yang et al (2001, 2002). Here the median-absolute value is used for preference to as to not re-center the M-values.

`normalizeMedianAbsValues` is also used to scale the A-values when scale-normalization is applied to an `MAList` object.

### Value

A numeric matrix of the same size as that input which has been scaled so that each column has the same median value (for `normalizeMedianValues`) or median-absolute value (for `normalizeMedianAbsValues`).

### Author(s)

Gordon Smyth

### See Also

An overview of LIMMA functions for normalization is given in [05.Normalization](#).

### Examples

```
M <- cbind(Array1=rnorm(10), Array2=2*rnorm(10))
normalizeMedianAbsValues(M)
```

---

normalizeQuantiles      *Normalize Columns of a Matrix to have the same Quantiles*

---

### Description

Normalize the columns of a matrix to have the same quantiles, allowing for missing values. Users do not normally need to call this function directly - use [normalizeBetweenArrays](#) instead.

### Usage

```
normalizeQuantiles(A, ties=TRUE)
```

### Arguments

A	numeric matrix. Missing values are allowed.
ties	logical. If TRUE, ties in each column of A are treated in careful way. tied values will be normalized to the mean of the corresponding pooled quantiles.

### Details

This function is intended to normalize single channel or A-value microarray intensities between arrays. Each quantile of each column is set to the mean of that quantile across arrays. The intention is to make all the normalized columns have the same empirical distribution. This will be exactly true if there are no missing values and no ties within the columns: the normalized columns are then simply permutations of one another.

If there are ties amongst the intensities for a particular array, then with `ties=FALSE` the ties are broken in an unpredictable order. If `ties=TRUE`, all the tied values for that array will be normalized to the same value, the average of the quantiles for the tied values.

### Value

A matrix of the same dimensions as A containing the normalized values.

### Author(s)

Gordon Smyth

### References

---

normalizeRobustSpline *Normalize Single Microarray Using Shrunk Robust Splines*

---

### Description

Normalize the M-values for a single microarray using robustly fitted regression splines and empirical Bayes shrinkage.

### Usage

```
normalizeRobustSpline(M,A,layout=NULL,df=5,method="M")
```

### Arguments

M	numeric vector of M-values
A	numeric vector of A-values
layout	list specifying the dimensions of the spot matrix and the grid matrix. Defaults to a single group for the whole array.
df	degrees of freedom for regression spline, i.e., the number of regression coefficients and the number of knots
method	choices are "M" for M-estimation or "MM" for high breakdown point regression

### Details

This function implements an idea similar to print-tip loess normalization but uses regression splines in place of the loess curves and uses empirical Bayes ideas to shrink the individual print-tip curves towards a common value. This allows the technique to introduce less noise into good quality arrays with little spatial variation while still giving good results on arrays with strong spatial variation.

The original motivation for the robustspline method was to use whole-array information to moderate the normalization curves used for the individual print-tip groups. This was an important issue for academically printed spotted two-color microarrays, especially when some of the print-tip groups contained relatively few spots. In these situations, robust spline normalization ensures stable results even for print-tip groups with few spots.

Modern commercial two colour arrays do not usually have print tips, so in effect the whole array is a single print-tip group, and so the need for moderating individual curves is gone. Robustspline normalization can still be used for data from these arrays, in which case a single normalization curve is estimated. In this situation, the method is closely analogous to global loess, with a regression spline replacing the loess curve and with robust regression replacing the loess robustifying weights. Robust spline normalization with method="MM" has potential advantages over global loess normalization when there a lot of differential expression or the differential expression is assymmetric, because of the increased level of robustness. The potential advantages of this approach have not been fully explored in a refereed publication however.

### Value

Numeric vector containing normalized M-values.

### Author(s)

Gordon Smyth

## See Also

normalizeRobustSpline uses ns in the splines package to specify regression splines and rlm in the MASS package for robust regression.

This function is usually accessed through [normalizeWithinArrays](#). An overview of LIMMA functions for normalization is given in [05.Normalization](#).

## Examples

```
A <- 1:100
M <- rnorm(100)
normalized.M <- normalizeRobustSpline(M,A)

# Usual usage
## Not run: MA <- normalizeWithinArrays(RG, method="robustspline")
```

---

normalizeVSN	<i>Variance Stabilizing Normalization (vsn)</i>
--------------	---

---

## Description

Apply variance stabilizing normalization (vsn) to limma data objects.

## Usage

```
normalizeVSN(x, ...)
```

## Arguments

x                    a numeric matrix, EListRaw or RGList object.  
...                   other arguments are passed to vsn

## Details

This is an interface to the vsnMatrix function from the vsn package. The input x should contain raw intensities. If x contains background and well as foreground intensities, these will be subtracted from the foreground intensities before vsnMatrix is called.

Note that the vsn algorithm performs background correction and normalization simultaneously. If the data are from two-color microarrays, then the red and green intensities are treated as if they were single channel data, i.e., red and green channels from the same array are treated as unpaired. This algorithm is therefore separate from the backgroundCorrection, normalizeWithinArrays, then normalizeBetweenArrays paradigm used elsewhere in the limma package.

**Value**

The class of the output depends on the input. If `x` is a matrix, then the result is a matrix of the same size. If `x` is an `EListRaw` object, then an `EList` object with expression values on the log<sub>2</sub> scale is produced. For `x` is an `RGList`, then an `MAList` object with M and A-values on the log<sub>2</sub> scale is produced.

**See Also**

An overview of LIMMA functions for normalization is given in [05.Normalization](#).

See also `vsMatrix` in the `vs` package.

**Examples**

```
ngenes <- 100
narrays <- 4
x <- matrix(rnorm(ngenes*narrays),100,4)
y <- normalizeVSN(x)
```

---

normalizeWithinArrays *Normalize Within Arrays*

---

**Description**

Normalize the expression log-ratios for one or more two-colour spotted microarray experiments so that the log-ratios average to zero within each array or sub-array.

**Usage**

```
normalizeWithinArrays(object, layout, method="printtiploess", weights=object$weights,
                      span=0.3, iterations=4, controlspots=NULL, df=5, robust="M",
                      bc.method="subtract", offset=0)
MA.RG(object, bc.method="subtract", offset=0)
RG.MA(object)
```

**Arguments**

<code>object</code>	object of class <code>list</code> , <code>RGList</code> or <code>MAList</code> containing red and green intensities constituting two-color microarray data.
<code>layout</code>	list specifying the dimensions of the spot matrix and the grid matrix. For details see <a href="#">PrintLayout-class</a> .

method	character string specifying the normalization method. Choices are "none", "median", "loess", "printtiploess", "composite", "control" and "robustspline". A partial string sufficient to uniquely identify the choice is permitted.
weights	numeric matrix or vector of the same size and shape as the components of object containing spot quality weights.
span	numeric scalar giving the smoothing parameter for the loess fit
iterations	number of iterations used in loess fitting. More iterations give a more robust fit.
controlspots	numeric or logical vector specifying the subset of spots which are non-differentially-expressed control spots, for use with method="composite" or method="control".
df	degrees of freedom for spline if method="robustspline".
robust	robust regression method if method="robustspline". Choices are "M" or "MM".
bc.method	character string specifying background correct method, see <a href="#">backgroundCorrect</a> for options.
offset	numeric value, intensity offset used when computing log-ratios, see <a href="#">backgroundCorrect</a> .

## Details

Normalization is intended to remove from the expression measures any systematic trends which arise from the microarray technology rather than from differences between the probes or between the target RNA samples hybridized to the arrays.

This function normalizes M-values (log-ratios) for dye-bias within each array. Apart from method="none" and method="median", all the normalization methods make use of the relationship between dye-bias and intensity. Method "none" computes M-values and A-values but does no normalization. Method "median" subtracts the weighted median from the M-values for each array.

The loess normalization methods ("loess", "printtiploess" and "composite") were proposed by Yang et al (2001, 2002). Smyth and Speed (2003) review these methods and describe how the methods are implemented in the limma package, including choices of tuning parameters. More information on the loess control parameters span and iterations can be found under [loessFit](#). The default values used here are equivalent to those for the older function `stat.ma` in the `sma` package.

Oshlack et al (2004) consider the special issues that arise when a large proportion of probes are differentially expressed. They propose an improved version of composite loess normalization, which is implemented in the "control" method. This fits a global loess curve through a set of control spots, such as a whole-library titration series, and applies that curve to all the other spots.

The "robustspline" method calls [normalizeRobustSpline](#). See that function for more documentation.

`MA.RG` converts an unlogged `RGList` object into an `MAList` object. `MA.RG(object)` is equivalent to `normalizeWithinArrays(object, method="none")`.

`RG.MA(object)` converts back from an `MAList` object to a `RGList` object with unlogged intensities.

`weights` is normally a matrix giving a quality weight for every spot on every array. If `weights` is instead a vector or a matrix with only one column, then the weights will be assumed to be the same for every array, i.e., the weights will be probe-specific rather than spot-specific.

## Value

An object of class `MAList`. Any components found in object will preserved except for R, G, Rb, Gb and other.

**See Also**

An overview of limma functions for normalization is given in [05.Normalization](#). In particular, see [normalizeBetweenArrays](#) for between-array normalization.

The original loess normalization function was the `statma` function in the `sma` package. `normalizeWithinArrays` is a direct generalization of that function, with more options and with support for quantitative spot quality weights.

A different implementation of loess normalization methods, with potentially different behavior, is provided by the `maNorm` in the `marray` package.

---

 normexp.fit

---

*Fit Normal+Exp Convolution Model to Observed Intensities*

---

**Description**

Fit the normal+exponential convolution model to a vector of observed intensities. The normal part represents the background and the exponential part represents the signal intensities. This function is called by `backgroundCorrect` and is not normally called directly by users.

**Usage**

```
normexp.fit(x, method="saddle", n.pts=NULL, trace=FALSE)
```

**Arguments**

<code>x</code>	numeric vector of (background corrected) intensities
<code>method</code>	method used to estimate the three parameters. Choices for <code>normexp.fit</code> are "mle", "saddle", "rma" and "rma75".
<code>n.pts</code>	number of quantiles of <code>x</code> to use for the fit. If <code>NULL</code> then all values of <code>x</code> will be used.
<code>trace</code>	logical, if <code>TRUE</code> , tracing information on the progress of the optimization is given.

## Details

The Normal+Exp (normexp) convolution model is a mathematical model representing microarray intensity data for the purposes of background correction. It was proposed originally as part of the RMA algorithm for Affymetrix microarray data. For two-color microarray data, the normexp background correction method was introduced and compared with other methods by Ritchie et al (2007).

This function uses maximum likelihood estimation to fit the normexp model to background-corrected intensities. The model assumes that the observed intensities are the sum of background and signal components, the background being normal and the signal being exponential distributed.

The likelihood may be computed exactly (method="mle") or approximated using a saddle-point approximation (method="saddle"). The saddle-point approximation was proposed by Ritchie et al (2007). Silver et al (2008) added some computational refinements to the saddle-point approximation, making it more reliable in practice, and developed the exact likelihood maximization algorithm. The "mle" method uses the best performing algorithm from Silver et al (2008), which calls the optimization function `nlminb` with analytic first and second derivatives. Derivatives are computed with respect to the normal-mean, the log-normal-variance and the log-exponential-mean.

Two ad-hoc estimators are also available which do not require iterative estimation. "rma" results in a call to the `bg.parameters` function of the `affy` package. This provides the kernel estimation method that is part of the RMA algorithm for Affymetrix data. "rma75" uses the similar but less biased RMA-75 method from McGee and Chen (2006).

If the length `x` is very large, it may be worth saving computation time by setting `n.pts` to a value less than the total number of probes, for example `n.pts=2^14`.

## Value

A list containing the components

<code>par</code>	numeric vector giving estimated values of the mean and log-standard-deviation of the background-normal part and the log-mean of the signal-exponential part.
<code>m2loglik</code>	numeric scalar giving minus twice the maximized log-likelihood
<code>convergence</code>	integer code indicating successful convergence or otherwise of the optimization.

out <- normexp.fit(x)
normexp.signal(out$par, x=x)
```

---

normexp.fit.control     *Normexp Model Parameter Estimation Aided by Negative Controls*

---

**Description**

The mean and log-standard-deviation of the background-normal part of the normexp+exponential convolution model is estimated as the mean and log-standard deviation of intensities from negative control probes. The log-mean of the signal-exponential part is estimated as the log of the difference between signal mean and background mean.

**Usage**

```
normexp.fit.control(x, status=NULL, negctrl="negative", regular="regular", robust=FALSE)
```

**Arguments**

x	object of class <code>EListRaw-class</code> or matrix containing raw intensities for regular and control probes for a series of microarrays
status	character vector giving probe types.
negctrl	character string identifier for negative control probes.
regular	character string identifier for regular probes.
robust	logical. Should robust estimators be used for the background mean and standard deviation?

**Details**

x has to contain raw expression intensities from both regular probes and negative control probes.

The probe type information for an object of `EListRaw-class` is normally saved in the Status column of its genes component. However, it will be overridden by the status parameter if it is explicitly provided to this function. If x is a matrix object, the probe type information has to be provided through the status parameter of this function. Regular probes have the status regular. Negative control probes have the status indicated by negctrl, which is negative by default.

This function estimates parameters of the normal+exponential convolution model with the help of negative control probes. The mean and log-standard-deviation of the background-normal part of the normexp+exponential(normexp) convolution model are estimated as the mean and log-standard deviation of intensities from negative control probes respectively. The log-mean of the signal-exponential part is estimated as the log of the difference between signal mean and background mean. The signal mean is simply the mean of intensities from regular probes.

When negative control probes are not available, the [normexp.fit.detection.p](#) function can be used to estimate the normexp model parameters which infers the negative control probe intensities from regular probes by taking advantage of their detection p value information.

**Value**

A matrix containing estimated parameters with rows being arrays and with columns being parameters. Column names are mu, logsigma and logalpha.

Shi W, Oshlack A and Smyth GK (2010). Optimizing the noise versus bias trade-off for Illumina Whole Genome Expression BeadChips. *Nucleic Acids Research*, 38(22):e204. Epub 2010 Oct 6. PMID: 20929874

**See Also**

`nec` calls this function to get the parameters of the normal+exponential convolution model and then calls `normexp.signal` to perform the background correction.

`normexp.fit.detection.p` estimates the parameters in the normal+exponential convolution model using negative control probe intensities inferred from regular probes by using their detection p values information.

`normexp.fit` estimates normexp parameters using a saddle-point approximation or other methods.

An overview of background correction functions is given in [04.Background](#).

**Examples**

```
## Not run:
# read in BeadChip probe profile file and control profile file
x <- read.ilmn(files="sample probe profile", ctrlfiles="control probe profile")
# estimated normexp parameters
normexp.fit.control(x)
# normalization using control data
y <- neqc(x)

## End(Not run)
```

---

normexp.fit.detection.p

*Estimate Normexp Model Parameter Using Negative Controls Inferred from Regular Probes*

---

**Description**

Detection p values from Illumina BeadChip microarray data can be used to infer negative control probe intensities from regular probe intensities by using detection p value information when negative control data are not available. The inferred negative control intensities can then be used in the background correction in the same way as those control data outputted from BeadChip used in the `normexp.fit.control` function.

**Usage**

```
normexp.fit.detection.p(x, detection.p="Detection")
```

## Arguments

x	object of class EListRaw-class or matrix containing raw intensities of regular probes for a series of microarrays
detection.p	a character string giving the name of the component which contains detection p value information in x or a numeric matrix giving detection p values, Detection by default

## Details

This function estimates the normexp parameters in the same way as `normexp.fit.control` does, except that negative control probe intensities are inferred from regular probes by taking advantage of detection p value information rather than from the control probe profile outputted by BeadStudio.

Calculation of detection p values in Illumina BeadChip data is based on the rank of probe intensities in the list of negative control probe intensities. Therefore, the detection p values can be used to find regular probes which have expression intensities falling into the range of negative control probe intensities. These probes give a good approximation to the real negative control data and thus can be used to estimate the mean and standard deviation of background intensities when negative control data is not available.

If x is an EListRaw-class object, this function will try to look for the component which includes detection p value matrix in x when detection.p is a character string. This function assumes that this component is located within the other component in x. The component name specified by detection.p should be exactly the same as the name of the detection p value component in x. If detection.p is a matrix, then this matrix will be used as the detection p value data used in this function.

If x is an matrix object, then detection.p has to be a data matrix which includes detection p values.

When detection.p is a matrix, it has to have the same dimension as that of x.

This function will replace the detection p values with 1 subtracted by these values if high intensity probes have detection p values less than those from low intensity probes.

Note that when control data are available, the `normexp.fit.control` function should be used instead.

## Value

A matrix containing estimated parameters with rows being arrays and with columns being parameters. Column names are mu, logsigma and logalpha.

normexp.signal	<i>Expected Signal Given Observed Foreground Under Normal+Exp Model</i>
----------------	---

---

**Description**

Adjust foreground intensities for observed background using Normal+Exp Model. This function is called by backgroundCorrect and is not normally called directly by the user.

**Usage**

```
normexp.signal(par, x)
```

**Arguments**

par            numeric vector containing the parameters of the Normal+Exp distribution, see [normexp.fit](#) for details.

x              numeric vector of (background corrected) intensities

**Details**

In general the vector normmean is computed conditional on background at each spot.

**Value**

Numeric vector containing adjusted intensities.

plotDensities	<i>Plot Expression Densities</i>
---------------	----------------------------------

---

## Description

Plot the density of expression values for multiple arrays on the same plot.

## Usage

```
## S3 method for class 'RGList'
plotDensities(object, log=TRUE, group=NULL, col=NULL, main="RG Densities",
              bc.method="subtract", ...)
## S3 method for class 'MAList'
plotDensities(object, log=TRUE, group=NULL, col=NULL, main="RG Densities", ...)
## S3 method for class 'EListRaw'
plotDensities(object, log=TRUE, bc.method="subtract", ...)
## S3 method for class 'EList'
plotDensities(object, log=TRUE, ...)
## Default S3 method:
plotDensities(object, group=NULL, col=NULL, main=NULL, legend="topleft", ...)
```

## Arguments

object	an RGList, MAList, EListRaw or EList object containing expression data. Or any data object that can be coerced to a matrix.
log	logical, should densities be plotted on the log2 scale?
group	optional vector or factor classifying the arrays into groups. Should be same length as ncol(object).
col	optional vector of colors of the same length as the number of groups.
main	the main title for the plot.
bc.method	background subtraction method passed to <a href="#">backgroundCorrect</a> .

legend character string giving position to place legend. See [legend](#) for possible values. Can also be logical, with FALSE meaning no legend.

... other arguments are passed to plotDensities.default or [density](#).

### Details

This function is useful to display and contrast the distribution of expression values on different arrays. It can for example be used to display the effects of between-array normalization. See the section on between-array normalization in the [LIMMA User's Guide](#).

### Value

A plot is created on the current graphics device.

### Author(s)

Natalie Thorne and Gordon Smyth

### See Also

An overview of diagnostic plots in LIMMA is given in [09.Diagnostics](#). There is a section using plotDensities in conjunction with between-array normalization in the [LIMMA User's Guide](#).

This function uses [density](#) and [matplot](#).

### Examples

```
## Not run:
# Default is to plot red channels in red and green channels in green
plotDensities(MA)

# Alternatively colors
plotDensities(MA, col=c("red", "blue"))

# Color by group, with three groups:
plotDensities(MA, group=group, col=c("blue", "orange", "green"))

## End(Not run)
```

---

plotExonJunc

*Differential splicing plot with junctions*

---

### Description

Plot differential usage results by exons and junctions for the specified gene and highlight the significantly spliced exons and junctions.

### Usage

```
plotExonJunc(fit, coef=ncol(fit), geneid, genecolname=NULL, FDR=0.05, annotation=NULL)
```

**Arguments**

fit	MArrayLM fit object produced by <code>diffSplice</code> . Must have the Entrez gene ids for all the exons and junctions stored in <code>fit\$genes\$GeneID</code> , length information for all the exons and junctions stored in <code>fit\$genes\$Length</code> and the strand information stored in <code>fit\$genes\$Strand</code> . To distinguish between exons and junctions, <code>fit\$genes\$Length</code> has to be set to 1 for all the junctions.
coef	the coefficient (column) of fit for which differentially splicing is assessed.
geneid	character string, ID of the gene to plot.
genecolname	column name of <code>fit\$genes</code> containing <code>geneid</code> .
FDR	numeric, highlight exons and junctions with false discovery rate less than this cutoff. Red indicates up-regulation whereas blue indicates down-regulation. The FDR of the individual exon/junction is calculated based on the exon-level t-statistics test for differences between each exon/junction and all other exons/junctions for the same gene.
annotation	data frame containing the full exon annotation of the corresponding species. Must have the Entrez gene ids for all the exons stored in the <code>GeneID</code> column, start and end positions for all the exons stored in the <code>Start</code> and <code>End</code> columns, respectively.

**Details**

Plot differential usage results by exons and junctions for the specified gene. The significantly spliced individual exons are highlighted as red blocks if up-regulated and blue blocks if down-regulated. All other exons are displayed as black blocks. The significantly spliced individual junctions are highlighted as red lines if up-regulated and blue lines if down-regulated. All other junctions are displayed as black lines.

Since the `diffSplice` analysis is usually performed after filtering, the full annotation (e.g. the in-built annotation in `featureCounts`) is highly recommended for producing the plot. When annotation is provided, the filtered exons are displayed as grey blocks.

**Value**

A plot is created on the current graphics device.

**Author(s)**

Yunshun Chen and Gordon Smyth

**See Also**

**Examples**

```
## Not run:
# diffSplice analysis
v <- voom(dge, design)
fit <- lmFit(v, design)
ex <- diffSplice(fit, geneid="GeneID")

# Get full annotation from Rsubread
library(Rsubread)
```

```

annotation.full <- getInBuiltAnnotation("mm10")

# Make a plot
plotExonJunc(ex, geneid="Foxp1", genecolname="Symbol", annotation=annotation.full)

## End(Not run)

```

---

plotExons

*Plot exons of differentially expressed gene*

---

### Description

Plot exons of differentially expressed gene and mark the differentially expressed exons.

### Usage

```

plotExons(fit, coef = ncol(fit), geneid = NULL, genecolname = "GeneID",
          exoncolname = NULL, rank = 1L, FDR = 0.05)

```

### Arguments

fit	MArrayLM fit object produced by eBayes.
coef	the coefficient (column) of fit for which differential expression is assessed.
geneid	character string, ID of the gene to plot.
genecolname	character string for the column name of fit\$genes containing gene IDs. Defaults to "GeneID" for Entrez Gene ID.
exoncolname	character string for the column name of fit\$genes containing exon IDs.
rank	integer, if geneid=NULL then this ranked gene will be plotted.
FDR	numeric, mark differentially expressed exons with false discovery rate less than this cutoff.

### Details

Plots log<sub>2</sub>-fold-change by exon for the specified gene and highlight the differentially expressed exons. Show annotations such as GeneID, Symbol and Strand if available as title for the gene to plot. The significantly differentially expressed individual exons are highlighted as red dots for up-regulation and as blue dots for down-regulation. The size of the dots are weighted by its significance.

### Value

A plot is created on the current graphics device.

**Examples**

```
## Not run:
fit <- lmFit(y,design)
fit <- eBayes(fit)
plotExons(fit)
plotExons(fit, exoncolname = "Start", rank = 1)
plotExons(fit, geneid = "ps", genecolname = "Symbol", exoncolname = "Start")

## End(Not run)
```

plotFB

*FB-Plot***Description**

Creates foreground-background plots.

**Usage**

```
## S3 method for class 'RGList'
plotFB(x, array=1, lim="separate", pch=16, cex=0.2, ...)
## S3 method for class 'EListRaw'
plotFB(x, array=1, pch=16, cex=0.2, ...)
```

**Arguments**

x	an RGList or EListRaw object.
array	integer giving the array to be plotted.
lim	character string indicating whether the red and green plots should have "separate" or "common" x- and y- co-ordinate limits.
pch	vector or list of plotting characters. Defaults to integer code 16.
cex	numeric vector of plot symbol expansions.
...	any other arguments are passed to plot

**Details**

A foreground-background plot is a plot of log<sub>2</sub>-foreground vs log<sub>2</sub>-background for a particular array. For two-color arrays, this function produces a pair of plots, one for the green channel and one for the red.

See [points](#) for possible values for pch, col and cex.

**Value**

A plot is created on the current graphics device.

plotlines	<i>plotlines</i>
-----------	------------------

---

**Description**

Time course style plot of expression data.

**Usage**

```
plotlines(x, first.column.origin=FALSE, xlab="Column", ylab="x", col="black", lwd=1, ...)
```

**Arguments**

x	numeric matrix or object containing expression data.
first.column.origin	logical, should the lines be started from zero?
xlab	x-axis label
ylab	y-axis label
col	vector of colors for lines
lwd	line width multiplier
...	any other arguments are passed to plot

**Details**

Plots a line for each probe.

**Value**

A plot is created on the current graphics device.

plotMA

*MA-Plot of Expression Data*

---

### Description

Creates an MA-plot with color coding for control spots.

### Usage

```
## Default S3 method:
plotMA(object, array = 1, xlab = "Average log-expression",
        ylab = "Expression log-ratio (this sample vs others)",
        main = colnames(object)[array], status=NULL, ...)
## S3 method for class 'EList'
plotMA(object, array = 1, xlab = "Average log-expression",
        ylab = "Expression log-ratio (this sample vs others)",
        main = colnames(object)[array], status=object$genes$Status,
        zero.weights = FALSE, ...)
## S3 method for class 'RGList'
plotMA(object, array = 1, xlab = "A", ylab = "M",
        main = colnames(object)[array], status=object$genes$Status,
        zero.weights = FALSE, ...)
## S3 method for class 'MAList'
plotMA(object, array = 1, xlab = "A", ylab = "M",
        main = colnames(object)[array], status=object$genes$Status,
        zero.weights = FALSE, ...)
## S3 method for class 'MArrayLM'
plotMA(object, coef = ncol(object), xlab = "Average log-expression",
        ylab = "log-fold-change", main = colnames(object)[coef],
        status=object$genes$Status, zero.weights = FALSE, ...)
```

### Arguments

object	an RGList, MAList, EList, ExpressionSet or MArrayLM object. Alternatively a numeric matrix.
array	integer giving the array to be plotted.
coef	integer giving the linear model coefficient to be plotted.
xlab	character string, label for x-axis
ylab	character string, label for y-axis
main	character string, title for plot
status	vector giving the control status of each spot on the array, of same length as the number of rows of object. If NULL, then all points are plotted in the default color, symbol and size.
zero.weights	logical, should spots with zero or negative weights be plotted?
...	other arguments are passed to <a href="#">plotWithHighlights</a> .

## Details

An MA-plot is a plot of log-intensity ratios (M-values) versus log-intensity averages (A-values). See Ritchie et al (2015) for a brief historical review.

For two color data objects, a within-array MA-plot is produced with the M and A values computed from the two channels for the specified array. This is the same as a mean-difference plot (`mdplot`) with the red and green log<sub>2</sub>-intensities of the array providing the two columns.

For single channel data objects, a between-array MA-plot is produced. An artificial array is produced by averaging all the arrays other than the array specified. A mean-difference plot is then producing from the specified array and the artificial array. Note that this procedure reduces to an ordinary mean-difference plot when there are just two arrays total.

If object is an `MArrayLM` object, then the plot is an fitted model MA-plot in which the estimated coefficient is on the y-axis and the average A-value is on the x-axis.

The status vector can correspond to any grouping of the probes that is of interest. If object is a fitted model object, then status vector is often used to indicate statistical significance, so that differentially expressed points are highlighted. If object is a microarray data object, then status might distinguish control probes from regular probes so that different types of controls are highlighted.

The status can be included as the component `object$genes$Status` instead of being passed as an argument to `plotMA`.

See `plotWithHighlights` for how to set colors and graphics parameters for the highlighted and non-highlighted points.

## Value

A plot is created on the current graphics device.

## Note

The `plotMD` function provides the same functionality as `plotMA` with slightly different arguments.

## Author(s)

Gordon Smyth

## See Also

The driver function for `plotMA` is `plotWithHighlights`.

An overview of plot functions available in LIMMA is given in [09.Diagnostics](#).

## Examples

```
A <- runif(1000,4,16)
y <- A + matrix(rnorm(1000*3,sd=0.2),1000,3)
status <- rep(c(0,-1,1),c(950,40,10))
y[,1] <- y[,1] + status
```

```

plotMA(y, array=1, status=status, values=c(-1,1), hl.col=c("blue","red"))

MA <- new("MList")
MA$A <- runif(300,4,16)
MA$M <- rt(300,df=3)

# Spike-in values
MA$M[1:3] <- 0
MA$M[4:6] <- 3
MA$M[7:9] <- -3

status <- rep("Gene",300)
status[1:3] <- "M=0"
status[4:6] <- "M=3"
status[7:9] <- "M=-3"
values <- c("M=0","M=3","M=-3")
col <- c("blue","red","green")

plotMA(MA,main="MA-Plot with 12 spiked-in points",
       status=status, values=values, hl.col=col)

# Same as above but setting graphical parameters as attributes
attr(status,"values") <- values
attr(status,"col") <- col
plotMA(MA, main="MA-Plot with 12 spiked-in points", status=status)

# Same as above but passing status as part of object
MA$genes$Status <- status
plotMA(MA, main="MA-Plot with 12 spiked-in points")

# Change settings for background points
MA$genes$Status <- status
plotMA(MA, bg.pch=1, bg.cex=0.5)

```

---

plotMA3by2

*Write MA-Plots to Files*

---

## Description

Write MA-plots to files in PNG format, six plots to a file in a 3 by 2 grid arrangement.

## Usage

```

plotMA3by2(object, prefix="MA", path=NULL, main=colnames(object),
           zero.weights=FALSE, common.lim=TRUE, device="png", ...)

```

## Arguments

object	an MList, RGList, EListRaw or EList object, or a matrix containing log-intensities.
prefix	character string giving prefix to attach to file names
path	character string specifying directory for output files
main	character vector giving titles for plots

zero.weights	logical, should points with non-positive weights be plotted
common.lim	logical, should all plots on a page use the same axis limits
device	device driver for the plot. Choices are "png", "jpeg", "pdf", "postscript".
...	any other arguments are passed to plotMA

### Details

This function writes a series of graphic files to disk. Each file contains six MA-plots in three rows and two columns. The layout is optimized for A4-sized paper.

The graph format can be "png" or "jpeg", which are screen-resolution formats, or "pdf" or "postscript", which are loss-less formats. "png" is not available on every R platform. Note that "pdf" or "postscript" may produce very large files.

### Value

No value is returned, but one or more files are written to the working directory. The number of files is determined by the number of columns of object.

### Author(s)

Gordon Smyth

plotMD

*Mean-Difference Plot of Expression Data*

---

### Description

Creates a mean-difference plot (aka MA plot) with color coding for highlighted points.

### Usage

```
## Default S3 method:
plotMD(object, column = 1, xlab = "Average log-expression",
        ylab = "Expression log-ratio (this sample vs others)",
        main = colnames(object)[column], status=NULL, ...)
## S3 method for class 'EList'
plotMD(object, column = 1, array = NULL, xlab = "Average log-expression",
        ylab = "Expression log-ratio (this sample vs others)",
        main = colnames(object)[column], status=object$genes$Status,
        zero.weights = FALSE, ...)
## S3 method for class 'RGList'
plotMD(object, column = 1, array = NULL, xlab = "A", ylab = "M",
        main = colnames(object)[column], status=object$genes$Status,
        zero.weights = FALSE, ...)
## S3 method for class 'MAList'
```

```

plotMD(object, column = 1, array = NULL, xlab = "A", ylab = "M",
        main = colnames(object)[column], status=object$genes$Status,
        zero.weights = FALSE, ...)
## S3 method for class 'MArrayLM'
plotMD(object, column = ncol(object), coef = NULL, xlab = "Average log-expression",
        ylab = "log-fold-change", main = colnames(object)[column],
        status=object$genes$Status, zero.weights = FALSE, ...)

```

### Arguments

object	an RGList, MAList, EList, ExpressionSet or MArrayLM object. Alternatively a numeric matrix.
column	integer, column of object to be plotted.
array	alternative to column for microarray data objects. If specified, then column is ignored.
coef	alternative to column for fitted model objects. If specified, then column is ignored.
xlab	character string, label for x-axis
ylab	character string, label for y-axis
main	character string, title for plot
status	vector giving the control status of each spot on the array, of same length as the number of rows of object. If NULL, then all points are plotted in the default color, symbol and size.
zero.weights	logical, should spots with zero or negative weights be plotted?
...	other arguments are passed to <a href="#">plotWithHighlights</a> .

### Details

A mean-difference plot (MD-plot) is a plot of log-intensity ratios (differences) versus log-intensity averages (means). For two color data objects, a within-array MD-plot is produced with the M and A values computed from the two channels for the specified array. This is the same as a mean-difference plot ([mdplot](#)) with the red and green log<sub>2</sub>-intensities of the array providing the two columns.

For single channel data objects, a between-array MD-plot is produced. An artificial array is produced by averaging all the arrays other than the array specified. A mean-difference plot is then producing from the specified array and the artificial array. Note that this procedure reduces to an ordinary mean-difference plot when there are just two arrays total.

If object is an MArrayLM object, then the plot is an fitted model MD-plot in which the estimated coefficient is on the y-axis and the average A-value is on the x-axis.

The status vector can correspond to any grouping of the probes that is of interest. If object is a fitted model object, then status vector is often used to indicate statistical significance, so that differentially expressed points are highlighted. If object is a microarray data object, then status might distinguish control probes from regular probes so that different types of controls are highlighted.

The status can be included as the component object\$genes\$Status instead of being passed as an argument to plotMD.

See [plotWithHighlights](#) for how to set colors and graphics parameters for the highlighted and non-highlighted points.

**Value**

A plot is created on the current graphics device.

**Note**

This function is an alternative to plotMA, which was one of the original functions of the limma package in 2002. The history of mean-difference plots and MA-plots is reviewed in Ritchie et al (2015).

An overview of plot functions available in LIMMA is given in [09.Diagnostics](#).

**Examples**

```
A <- runif(1000,4,16)
y <- A + matrix(rnorm(1000*3,sd=0.2),1000,3)
status <- rep(c(0,-1,1),c(950,40,10))
y[,1] <- y[,1] + status
plotMD(y, column=1, status=status, values=c(-1,1), hl.col=c("blue","red"))

MA <- new("MAList")
MA$A <- runif(300,4,16)
MA$M <- rt(300,df=3)

# Spike-in values
MA$M[1:3] <- 0
MA$M[4:6] <- 3
MA$M[7:9] <- -3

status <- rep("Gene",300)
status[1:3] <- "M=0"
status[4:6] <- "M=3"
status[7:9] <- "M=-3"
values <- c("M=0","M=3","M=-3")
hl.col <- c("blue","red","green")

plotMD(MA,main="MA-Plot with 12 spiked-in points",
       status=status, values=values, hl.col=hl.col)

# Same as above but setting graphical parameters as attributes
attr(status,"values") <- values
attr(status,"col") <- hl.col
```

```

plotMD(MA, main="Mean-Difference Plot with 12 spiked-in points", status=status)

# Same as above but passing status as part of object
MA$genes$Status <- status
plotMD(MA, main="Mean-Difference Plot with 12 spiked-in points")

# Change settings for background points
MA$genes$Status <- status
plotMD(MA, bg.pch=1, bg.cex=0.5)

```

---

plotMDS	<i>Multidimensional scaling plot of distances between gene expression profiles</i>
---------	--

---

## Description

Plot samples on a two-dimensional scatterplot so that distances on the plot approximate the typical log<sub>2</sub> fold changes between the samples.

## Usage

```

## Default S3 method:
plotMDS(x, top = 500, labels = NULL, pch = NULL, cex = 1,
        dim.plot = c(1,2), ndim = max(dim.plot), gene.selection = "pairwise",
        xlab = NULL, ylab = NULL, plot = TRUE, ...)
## S3 method for class 'MDS'
plotMDS(x, labels = NULL, pch = NULL, cex = 1, dim.plot = NULL,
        xlab = NULL, ylab = NULL, ...)

```

## Arguments

x	any data object which can be coerced to a matrix, for example an ExpressionSet or an EList.
top	number of top genes used to calculate pairwise distances.
labels	character vector of sample names or labels. Defaults to colnames(x).
pch	plotting symbol or symbols. See <a href="#">points</a> for possible values. Ignored if labels is non-NULL.
cex	numeric vector of plot symbol expansions.
dim.plot	integer vector of length two specifying which principal components should be plotted.
ndim	number of dimensions in which data is to be represented.
gene.selection	character, "pairwise" to choose the top genes separately for each pairwise comparison between the samples or "common" to select the same genes for all comparisons.
xlab	title for the x-axis.
ylab	title for the y-axis.
plot	logical. If TRUE then a plot is created on the current graphics device.
...	any other arguments are passed to plot, and also to text (if pch is NULL).

## Details

This function is a variation on the usual multidimensional scaling (or principle coordinate) plot, in that a distance measure particularly appropriate for the microarray context is used. The distance between each pair of samples (columns) is the root-mean-square deviation (Euclidean distance) for the top top genes. Distances on the plot can be interpreted as *leading log2-fold-change*, meaning the typical (root-mean-square) log2-fold-change between the samples for the genes that distinguish those samples.

If `gene.selection` is "common", then the top genes are those with the largest standard deviations between samples. If `gene.selection` is "pairwise", then a different set of top genes is selected for each pair of samples. The pairwise feature selection may be appropriate for microarray data when different molecular pathways are relevant for distinguishing different pairs of samples.

If `pch=NULL`, then each sample is represented by a text label, defaulting to the column names of `x`. If `pch` is not `NULL`, then plotting symbols are used.

See [text](#) for possible values for `col` and `cex`.

## Value

If `plot=TRUE`, a plot is created on the current graphics device.

An object of class "MDS" is also invisibly returned. This is a list containing the following components:

<code>distance.matrix</code>	numeric matrix of pairwise distances between columns of <code>x</code>
<code>cmdscale.out</code>	output from the function <code>cmdscale</code> given the distance matrix
<code>dim.plot</code>	dimensions plotted
<code>x</code>	x-coordinates of plotted points
<code>y</code>	y-coordinates of plotted points
<code>gene.selection</code>	gene selection method

An overview of diagnostic functions available in LIMMA is given in [09.Diagnostics](#).

## Examples

```
# Simulate gene expression data for 1000 probes and 6 microarrays.
# Samples are in two groups
# First 50 probes are differentially expressed in second group
sd <- 0.3*sqrt(4/rchisq(1000,df=4))
x <- matrix(rnorm(1000*6,sd=sd),1000,6)
```

```

rownames(x) <- paste("Gene",1:1000)
x[1:50,4:6] <- x[1:50,4:6] + 2
# without labels, indexes of samples are plotted.
mds <- plotMDS(x, col=c(rep("black",3), rep("red",3)) )
# or labels can be provided, here group indicators:
plotMDS(mds, col=c(rep("black",3), rep("red",3)), labels= c(rep("Grp1",3), rep("Grp2",3)))

```

---

plotPrintTipLoess      *MA Plots by Print-Tip Group*

---

### Description

Creates a coplot giving MA-plots with loess curves by print-tip groups.

### Usage

```
plotPrintTipLoess(object,layout,array=1,span=0.4,...)
```

### Arguments

object	MAList or RGList object or list with components M containing log-ratios and A containing average intensities
layout	a list specifying the number of tip rows and columns and the number of spot rows and columns printed by each tip. Defaults to MA\$printer if that is non-null.
array	integer giving the array to be plotted. Corresponds to columns of M and A.
span	span of window for lowess curve
...	other arguments passed to panel.smooth

### Details

Note that spot quality weights in object are not used for computing the loess curves for this plot even though such weights would be used for loess normalization using `normalizeWithinArrays`.

### Value

A plot is created on the current graphics device. If there are missing values in the data, then the vector of row numbers for spots with missing values is invisibly returned, as for `coplot`.

plotRLDF

*Plot of regularized linear discriminant functions for microarray data***Description**

Plot regularized linear discriminant functions for classifying samples based on expression data.

**Usage**

```
plotRLDF(y, design = NULL, z = NULL, nprobes = 100, plot = TRUE,
         labels.y = NULL, labels.z = NULL, pch.y = NULL, pch.z = NULL,
         col.y = "black", col.z = "black",
         show.dimensions = c(1,2), ndim = max(show.dimensions),
         var.prior = NULL, df.prior = NULL, trend = FALSE, robust = FALSE, ...)
```

**Arguments**

y	the training dataset. Can be any data object which can be coerced to a matrix, such as ExpressionSet or EList.
design	design matrix defining the training groups to be distinguished. The first column is assumed to represent the intercept. Defaults to <code>model.matrix(~factor(labels.y))</code> .
z	the dataset to be classified. Can be any data object which can be coerced to a matrix, such as ExpressionSet or EList. Rows must correspond to rows of y.
nprobes	number of probes to be used for the calculations. The probes will be selected by moderated F statistic.
plot	logical, should a plot be created?
labels.y	character vector of sample names or labels in y. Defaults to <code>colnames(y)</code> or failing that to <code>1:n</code> .
labels.z	character vector of sample names or labels in z. Defaults to <code>colnames(z)</code> or failing that to <code>letters[1:n]</code> .
pch.y	plotting symbol or symbols for y. See <a href="#">points</a> for possible values. Takes precedence over labels.y if both are specified.
pch.z	plotting symbol or symbols for y. See <a href="#">points</a> for possible values. Takes precedence over labels.z if both are specified.
col.y	colors for the plotting labels.y.
col.z	colors for the plotting labels.z.
show.dimensions	integer vector of length two indicating which two discriminant functions to plot. Functions are in decreasing order of discriminatory power.
ndim	number of discriminant functions to compute
var.prior	prior variances, for regularizing the within-group covariance matrix. By default is estimated by <code>squeezeVar</code> .
df.prior	prior degrees of freedom for regularizing the within-group covariance matrix. By default is estimated by <code>squeezeVar</code> .
trend	logical, should a trend be estimated for var.prior? See <code>eBayes</code> for details. Only used if var.prior or df.prior are NULL.
robust	logical, should var.prior and df.prior be estimated robustly? See <code>eBayes</code> for details. Only used if var.prior or df.prior are NULL.
...	any other arguments are passed to plot.

**Details**

The function builds discriminant functions from the training data (*y*) and applies them to the test data (*z*). The method is a variation on classical linear discriminant functions (LDFs), in that the within-group covariance matrix is regularized to ensure that it is invertible, with eigenvalues bounded away from zero. The within-group covariance matrix is squeezed towards a diagonal matrix with empirical Bayes posterior variances as diagonal elements.

The calculations are based on a filtered list of probes. The `nprobes` probes with largest moderated F statistics are used to discriminate.

The `ndim` argument allows all required LDFs to be computed even though only two are plotted.

**Value**

If `plot=TRUE` a plot is created on the current graphics device. A list containing the following components is (invisibly) returned:

<code>training</code>	numeric matrix with <code>ncol(y)</code> rows and <code>ndim</code> columns containing discriminant functions evaluated for the training data.
<code>predicting</code>	numeric matrix with <code>ncol(z)</code> rows and <code>ndim</code> columns containing discriminant functions evaluated on the classification data.
<code>top</code>	integer vector of length <code>nprobes</code> giving indices of probes used.
<code>metagenes</code>	numeric matrix with <code>nprobes</code> rows and <code>ndim</code> columns containing probe weights defining each discriminant function.
<code>singular.values</code>	singular.values showing the predictive power of each discriminant function.
<code>rank</code>	maximum number of discriminant functions with singular.values greater than zero.
<code>var.prior</code>	numeric vector of prior variances.
<code>df.prior</code>	numeric vector of prior degrees of freedom.

**Note**

The default values for `df.prior` and `var.prior` were changed in `limma` 3.27.10. Previously these were preset values. Now the default is to estimate them using `squeezeVar`.

```

plotSA

*Sigma vs A plot for microarray linear model***Description**

Plot residual standard deviation versus average log expression for a fitted microarray linear model.

**Usage**

```
plotSA(fit, xlab = "Average log-expression", ylab = "sqrt(sigma)", zero.weights = FALSE,
       pch = 16, cex = 0.3, col = c("black","red"), ...)
```

**Arguments**

fit	an MArrayLM object.
xlab	label for x-axis
ylab	label for y-axis
zero.weights	logical, should genes with all zero weights be plotted?
pch	vector of codes for plotting characters.
cex	numeric, vector of expansion factors for plotting characters.
col	plotting colors for regular and outlier variances respectively.
...	any other arguments are passed to plot

**Details**

This plot is used to check the mean-variance relationship of the expression data, after fitting a linear model. A scatterplot of residual-variances vs average log-expression is created. The plot is especially useful for examining the mean-variance trend estimated by [eBayes](#) or [treat](#) with `trend=TRUE`. It can be considered as a routine diagnostic plot in the `limma-trend` pipeline.

If robust empirical Bayes was used to create `fit`, then outlier variances are highlighted in the color given by `col[2]`.

The y-axis is square-root `fit$sigma`, where `sigma` is the estimated residual standard deviation. The y-axis therefore corresponds to quarter-root variances. The y-axis was changed from `log2`-variance to quarter-root variance in `limma` version 3.31.21. The quarter-root scale matches the similar plot produced by the `voom` function and gives a better plot when some of the variances are close to zero.

See [points](#) for possible values for `pch` and `cex`.

**Value**

A plot is created on the current graphics device.

**Author(s)**

Gordon Smyth

---

plotSplice

*Differential splicing plot*

---

**Description**

Plot relative log-fold changes by exons for the specified gene and highlight the significantly spliced exons.

**Usage**

```
plotSplice(fit, coef=ncol(fit), geneid=NULL, genecolname=NULL, rank=1L, FDR = 0.05)
```

**Arguments**

fit	MArrayLM fit object produced by diffSplice.
coef	the coefficient (column) of fit for which differentially splicing is assessed.
geneid	character string, ID of the gene to plot.
genecolname	column name of fit\$genes containing gene IDs. Defaults to fit\$genecolname.
rank	integer, if geneid=NULL then this ranked gene will be plotted.
FDR	numeric, highlight exons as red dots with false discovery rate less than this cut-off. The FDR of the individual exon is calculated based on the exon-level t-statistics test for differences between each exon and all other exons for the same gene.

**Details**

Plot relative log<sub>2</sub>-fold-changes by exon for the specified gene. The relative logFC is the difference between the exon's logFC and the overall logFC for the gene, as computed by diffSplice. The significantly spliced individual exons are highlighted as red dots. The size of the red dots are weighted by its significance.

**Value**

A plot is created on the current graphics device.

Creates scatterplot, with optional size and color coding for points of special interest. This is the engine for plotMD and plotMA.

**Usage**

```
plotWithHighlights(x, y, status = NULL, values = NULL,
                  hl.pch = 16, hl.col = NULL, hl.cex = 1, legend = "topright",
                  bg.pch = 16, bg.col = "black", bg.cex = 0.3,
                  pch = NULL, col = NULL, cex = NULL, ...)
```

**Arguments**

x	numeric vector.
y	numeric vector.
status	character vector giving the control status of each point, of same length as x and y. If NULL, then all points are plotted in the background color, symbol and size.
values	character vector giving values of status to be highlighted on the plot. Defaults to unique values of status in decreasing order of frequency, with the most frequent value set as the background value. Ignored if there is no status vector.
hl.pch	vector of plotting characters for highlighted points, either of unit length or of same length as values. Ignored if there is no status vector.
hl.col	vector of colors for highlighted points, either of unit length or of same length as values. Defaults to 1+1:length(values). Ignored if there is no status vector.
hl.cex	numeric vector of plot symbol expansions for highlighted points, either of unit length or of same length as values. Ignored if there is no status vector.
legend	character string giving position to place legend. See <a href="#">legend</a> for possible values. Can also be logical, with FALSE meaning no legend. Ignored if there is no status vector.
bg.pch	plotting character for background (non-highlighted) points.
bg.col	color for background (non-highlighted) points.
bg.cex	plot symbol expansion for background (non-highlighted) points.
pch	synonym for hl.pch allowed for backward compatibility.
col	synonym for hl.col allowed for backward compatibility.
cex	synonym for hl.cex allowed for backward compatibility.
...	other arguments are passed to plot.

## Details

This function produces a scatterplot in which the highlighted points are, by default, larger and colored compared to background points.

The status vector establishes the status of each point and values indicates which values of status should be highlighted. If values=NULL, then the most common value of status is assumed to correspond to background points and all other values are highlighted.

The arguments hl.pch, hl.col and hl.cex give graphics settings for highlighted points. By default, highlighted points are larger than background points and a different color is used for each distinct highlighted value.

The arguments bg.pch, bg.col and bg.cex give the graphics settings for non-highlighted (background) points. The same settings are used for all background points.

The arguments values, pch, col and cex can be included as attributes to status instead of being passed as arguments to plotWithHighlights. This is for compatibility with [controlStatus](#).

See [points](#) for possible values for the graphics parameters.

## Value

A plot is created on the current graphics device.

y <- status + rnorm(1000, sd=0.2)
plotWithHighlights(x, y, status=status)
```

## Description

Compute the Satterthwaite (1946) approximation to the distribution of a weighted sum of sample variances.

**Usage**

```
poolVar(var, df=n-1, multiplier=1/n, n)
```

**Arguments**

var	numeric vector of independent sample variances
df	numeric vector of degrees of freedom for the sample variances
multiplier	numeric vector giving multipliers for the sample variances
n	numeric vector of sample sizes

**Details**

The sample variances `var` are assumed to follow scaled chi-square distributions. A scaled chi-square approximation is found for the distribution of `sum(multiplier * var)` by equating first and second moments. On output the sum to be approximated is equal to `multiplier * var` which follows approximately a scaled chisquare distribution on `df` degrees of freedom. The approximation was proposed by Satterthwaite (1946).

If there are only two groups and the degrees of freedom are one less than the sample sizes then this gives the denominator of Welch's t-test for unequal variances.

**Value**

A list with components

var	effective pooled sample variance
df	effective pooled degrees of freedom
multiplier	pooled multiplier

**Examples**

```
# Welch's t-test with unequal variances
x <- rnorm(10,mean=1,sd=2)
y <- rnorm(20,mean=2,sd=1)
s2 <- c(var(x),var(y))
n <- c(10,20)
out <- poolVar(var=s2,n=n)
```

```
tstat <- (mean(x)-mean(y)) / sqrt(out$var*out$multiplier)
pvalue <- 2*pt(-abs(tstat),df=out$df)
# Equivalent to t.test(x,y)
```

---

predFCm

*Predictive log fold change for microarrays*

---

## Description

Calculate the predictive log fold change for a particular coefficient from a fit object.

## Usage

```
predFCm(fit, coef=2, var.indep.of.fc=TRUE, all.de=TRUE, prop.true.null.method="lfdr")
```

## Arguments

fit	an MArrayLM fitted model object produced by lmFit and eBayes
coef	integer vector indicating which columns in the fit object are to be shrunk
var.indep.of.fc	assume the genewise variances are independent of genewise fold changes?
all.de	assume all genes have a non-zero true fold change (TRUE)? If FALSE, then the proportion of truly non-differentially (non-DE) genes expressed will be estimated.
prop.true.null.method	method used to estimate proportion of truly non-DE genes. See <a href="#">propTrueNull</a> for possible values.

## Details

The predictive log fold changes are calculated as the posterior mean log fold changes in the empirical Bayes hierarchical model. We call them predictive log fold changes because they are the best prediction of what the log fold change will be for each gene in a comparable future experiment.

The log fold changes are shrunk towards zero depending on how variable they are. The `var.indep.of.fc` argument specifies whether the prior belief is that the log fold changes are independent of the variability of the genes or whether the log fold changes increase with increasing variability of the genes.

If `all.de=TRUE`, then all genes are assumed to have a non-zero log fold change, even if quite small. If `all.de=FALSE`, then some genes are assumed to have log fold changes exactly zero. The proportion of non-DE genes is estimated and taken into account in the calculation.

## Value

numeric vector of predictive (shrunk) log fold changes

## Author(s)

Belinda Phipson and Gordon Smyth

```
# Simulate gene expression data,
# 6 microarrays with 1000 genes on each array
set.seed(2004)
y <- matrix(rnorm(6000),ncol=4)

# two experimental groups and one control group with two replicates each
group <- factor(c("A", "A", "B", "B"))
design <- model.matrix(~group)

# fit a linear model
fit <- lmFit(y,design)
fit <- eBayes(fit)

# output predictive log fold changes for first 5 genes
pfc <- predFCm(fit,coef=2)
```

---

printHead

*Print Leading Rows of Large Objects*

---

## Description

Print the leading rows of a large vector, matrix or data.frame. This function is used by show methods for data classes defined in LIMMA.

## Usage

```
printHead(x)
```

## Arguments

x                    any object

## Details

If x is a vector with more than 20 elements, then printHead(x) prints only the first 5 elements. If x is a matrix or data.frame with more than 10 rows, then printHead(x) prints only the first 5 rows. Any other type of object is printed normally.

---

PrintLayout	<i>Print Layout - class</i>
-------------	-----------------------------

---

**Description**

A list-based class for storing information about the process used to print spots on a microarray.

PrintLayout objects can be created using [getLayout](#). The printer component of an RGList or MAList object is of this class.

**Slots/List Components**

Objects of this class contains no slots but should contain the following list components:

ngrid.r: number of grid rows on the arrays  
 ngrid.c: number of grid columns on the arrays  
 nspot.r: number of rows of spots in each grid  
 nspot.c: number of columns of spots in each grid  
 ndups: number of duplicates of each DNA clone, i.e., number of times print-head dips into each well of DNA  
 spacing: number of spots between duplicate spots. Only applicable if ndups>1. spacing=1 for side-by-side spots by row  
 npins: actual number of pins or tips on the print-head  
 start: character string giving position of the spot printed first in each grid. Choices are "topleft" or "topright" and

**Author(s)**

Gordon Smyth

**See Also**

[02.Classes](#) gives an overview of all the classes defined by this package.

**Examples**

```
# Settings for Swirl and ApoAI example data sets in User's Guide
printer <- list(ngrid.r=4, ngrid.c=4, nspot.r=22, nspot.c=24,
              ndups=1, spacing=1, npins=16, start="topleft")

# Typical settings at the Australian Genome Research Facility

# Full pin set, duplicates side-by-side on same row
printer <- list(ngrid.r=12, ngrid.c=4, nspot.r=20, nspot.c=20,
              ndups=2, spacing=1, npins=48, start="topright")

# Half pin set, duplicates in top and lower half of slide
printer <- list(ngrid.r=12, ngrid.c=4, nspot.r=20, nspot.c=20,
              ndups=2, spacing=9600, npins=24, start="topright")
```

---

 printorder

*Identify Order in which Spots were Printed*

---

**Description**

Identify order in which spots were printed and the 384-well plate from which they were printed.

**Usage**

```
printorder(layout, ndups=1, spacing="columns", npins, start="topleft")
```

**Arguments**

layout	list with the components <code>ngrid.r</code> , <code>ngrid.c</code> , <code>nspot.r</code> and <code>nspot.c</code> , or an <code>RGList</code> or <code>MAList</code> object from which the printer layout may be extracted.
ndups	number of duplicate spots, i.e., number of times print-head dips into each well
spacing	character string indicating layout of duplicate spots. Choices are "columns", "rows" or "topbottom".
npins	actual number of pins or tips on the print-head
start	character string giving position of the spot printed first in each grid. Choices are "topleft" or "topright" and partial matches are accepted.

**Details**

In most cases the printer-head contains the `layout$ngrid.r` times `layout$ngrid.c` pins or tips and the array is printed using `layout$nspot.r` times `layout$nspot.c` dips of the head. The plate holding the DNA to be printed is assumed to have 384 wells in 16 rows and 24 columns.

`ndups` indicates the number of spots printed from each well. The replicate spots from multiple dips into the same wells are assumed to be side-by-side by columns (`spacing="columns"`), by rows (`spacing="rows"`) or in the top and bottom halves of the array (`spacing="topbottom"`).

In some cases a smaller number of physical pins is used and the total number of grids is built up by effectively printing two or more sub-arrays on the same slide. In this case the number of grids should be a multiple of the number of pins.

Printing is assumed to proceed by rows within in each grid starting either from the top-left or the top-right.

**Value**

List with components

printorder	numeric vector giving printorder of each spot, i.e., which dip of the print-head was used to print it
plate	numeric vector giving plate number from which each spot was printed
plate.r	numeric vector giving plate-row number of the well from which each spot was printed
plate.c	numeric vector giving plate-column number of the well from which each spot was printed
plateposition	character vector summarizing plate number and plate position of the well from which each spot was printed with letters for plate rows and number for columns. For example 02B13 is second row, 13th column, of the second plate.

**Author(s)**

Gordon Smyth

**See Also**[normalizeForPrintorder](#).An overview of LIMMA functions for reading data is given in [03.ReadingData](#).**Examples**

```
printorder(list(ngrid.r=2,ngrid.c=2,nspot.r=12,nspot.c=8))
```

---

<code>printtipWeights</code>	<i>Sub-array Quality Weights</i>
------------------------------	----------------------------------

---

**Description**

Estimates relative quality weights for each sub-array in a multi-array experiment.

**Usage**

```
printtipWeights(object, design = NULL, weights = NULL, method = "genebygene", layout,
                maxiter = 50, tol = 1e-10, trace=FALSE)
```

**Arguments**

<code>object</code>	object of class <code>numeric</code> , <code>matrix</code> , <code>MAList</code> , <code>marrayNorm</code> , or <code>ExpressionSet</code> containing log-ratios or log-values of expression for a series of spotted microarrays.
<code>design</code>	the design matrix of the microarray experiment, with rows corresponding to arrays and columns to coefficients to be estimated. Defaults to the unit vector meaning that the arrays are treated as replicates.
<code>weights</code>	optional numeric matrix containing prior weights for each spot.
<code>method</code>	character string specifying the estimating algorithm to be used. Choices are "genebygene" and "reml".
<code>layout</code>	list specifying the dimensions of the spot matrix and the grid matrix. For details see <a href="#">PrintLayout-class</a> .
<code>maxiter</code>	maximum number of iterations allowed.
<code>tol</code>	convergence tolerance.
<code>trace</code>	logical variable. If true then output diagnostic information at each iteration of "reml" algorithm.

## Details

The relative reliability of each sub-array (print-tip group) is estimated by measuring how well the expression values for that sub-array follow the linear model.

The method described in Ritchie et al (2006) and implemented in the `arrayWeights` function is adapted for this purpose. A heteroscedastic model is fitted to the expression values for each gene by calling the function `lm.wfit`. The dispersion model is fitted to the squared residuals from the mean fit, and is set up to have sub-array specific coefficients, which are updated in either full REML scoring iterations, or using an efficient gene-by-gene update algorithm. The final estimates of the sub-array variances are converted to weights.

The data object `object` is interpreted as for `lmFit`. In particular, the arguments `design`, `weights` and `layout` will be extracted from the data object if available and do not normally need to be set explicitly in the call; if any of these are set in the call then they will over-ride the slots or components in the data object.

## Value

A matrix of sub-array weights.

## Author(s)

Matthew Ritchie and Gordon Smyth

---

propexpr	<i>Estimate Proportion of Expressed Probes</i>
----------	--

---

### Description

Estimate the proportion of microarray probes which are expressed in each array.

### Usage

```
propexpr(x, neg.x=NULL, status=x$genes$Status, labels=c("negative","regular"))
```

### Arguments

x	matrix or similar object containing raw intensities for a set of arrays.
neg.x	matrix or similar object containing raw intensities for negative control probes for the same arrays. If NULL, then negative controls must be provided in x.
status	character vector specifying control type of each probe. Only used if neg.x is NULL.
labels	character vector giving the status values for negative control probes and regular (non-control) probes respectively. If of length 1, then all probes other than the negative controls are assumed to be regular. Only used if neg.x is NULL.

### Details

This function estimates the overall proportion of probes on each microarray that correspond to expressed genes using the method of Shi et al (2010). The function is especially useful for Illumina BeadChips arrays, although it can in principle be applied to any platform with good quality negative controls.

The negative controls can be supplied either as rows of x or as a separate matrix. If supplied as rows of x, then the negative controls are identified by the status vector. x might also include other types of control probes, but these will be ignored in the calculation.

Illumina BeadChip arrays contain 750~1600 negative control probes. If read.idat is used to read Illumina expression IDAT files, then the control probes will be populated as rows of the output ELiStRaw object, and the vector x\$genes\$Status will be set to identify control probes.

Alternatively, expression values can be exported from Illumina's GenomeStudio software as tab-delimited text files. In this case, the control probes are usually written to a separate file from the regular probes.

### Value

Numeric vector giving the proportions of expressed probes in each array.

### Author(s)

Wei Shi and Gordon Smyth

## References

# Read text files exported from GenomeStudio
x <- read.ilmn(files = "sample probe profile.txt",
              ctrlfiles = "control probe profile.txt")
propexpr(x)

## End(Not run)
```

---

propTrueNull

*Estimate Proportion of True Null Hypotheses*

---

## Description

Estimate the proportion of true null hypotheses from a vector of p-values.

## Usage

```
propTrueNull(p, method="lfdr", nbins=20, ...)
convest(p, niter=100, plot=FALSE, report=FALSE, file="", tol=1e-6)
```

## Arguments

p	numeric vector of p-values.
method	estimation method. Choices are "lfdr", "mean", "hist" or "convest".
nbins	number of histogram bins (if method="hist").
niter	number of iterations to be used in fitting the convex, decreasing density for the p-values.
plot	logical, should updated plots of fitted convex decreasing p-value density be produced at each iteration?
report	logical, should the estimated proportion be printed at each iteration?
file	name of file to which to write the report. Defaults to standard output.
tol	accuracy of the bisectional search for finding a new convex combination of the current iterate and the mixing density
...	other arguments are passed to convest if method="convest".

## Details

The proportion of true null hypotheses in a collection of hypothesis tests is often denoted  $\pi_0$ . This function estimates  $\pi_0$  from a vector of p-values.

method="lfdr" implements the method of Phipson (2013) based on averaging local false discovery rates across the p-values.

method="mean" is a very simple method based on averaging the p-values. It gives a slightly smaller estimate than  $2 \times \text{mean}(p)$ .

method="hist" implements the histogram method of Mosig et al (2001) and Nettleton et al (2006).

method="convest" calls convest, which implements the method of Langaas et al (2005) based on a convex decreasing density estimate.

## Value

Numeric value in the interval [0,1] representing the estimated proportion of true null hypotheses.

## Author(s)

Belinda Phipson and Gordon Smyth for propTrueNull. Egil Ferkingstad, Mette Langaas and Marcus Davy for convest.

## References

---

protectMetachar	<i>Protect Metacharacters</i>
-----------------	-------------------------------

---

## Description

Add backslashes before any metacharacters found in a string.

## Usage

```
protectMetachar(x)
```

## Arguments

x                    character vector

## Details

This function is used to protect strings containing metacharacters so that the metacharacters can be treated as ordinary characters in string matching functions operations.

## Value

A character vector of the same length as x in which two backslashes have been inserted before any metacharacter.

## Author(s)

Gordon Smyth

## See Also

An overview of LIMMA functions for reading data is given in [03.ReadingData](#).

## Examples

```
# without protectMetachar, this would be no match
grep(protectMetachar("Ch1 (mean)"), "Ch1 (mean)")
```

qqt

*Student's t or Fisher's F Quantile-Quantile Plot***Description**

Plots the quantiles of a data sample against the theoretical quantiles of a Student's t distribution.

**Usage**

```
qqt(y, df = Inf, ylim = range(y), main = "Student's t Q-Q Plot",
    xlab = "Theoretical Quantiles", ylab = "Sample Quantiles", plot.it = TRUE, ...)
qqf(y, df1, df2, ylim=range(y), main= "F Distribution Q-Q Plot",
    xlab = "Theoretical Quantiles", ylab = "Sample Quantiles", plot.it = TRUE, ...)
```

**Arguments**

y	a numeric vector or array containing the data sample
df	degrees of freedom for the t-distribution. The default df=Inf represents the normal distribution.
df1	numerator degrees of freedom for the F-distribution.
df2	denominator degrees of freedom for the F-distribution.
ylim	plotting range for y
main	main title for the plot
xlab	x-axis title for the plot
ylab	y-axis title for the plot
plot.it	whether or not to produce a plot
...	other arguments to be passed to plot

**Details**

This function is analogous to `qqnorm` for normal probability plots. In fact `qqt(y, df=Inf)` is identical to `qqnorm(y)` in all respects except the default title on the plot.

**Value**

A list is invisibly returned containing the values plotted in the QQ-plot:

x	theoretical quantiles of the t-distribution or F-distribution
y	the data sample, same as input y

**Author(s)**

Gordon Smyth

**See Also**

[qqnorm](#)

**Examples**

```
# See also the lmFit examples

y <- rt(50,df=4)
qqt(y,df=4)
abline(0,1)
```

---

QualityWeights

*Spot Quality Weights*

---

**Description**

Functions to calculate quality weights for individual spots based on image analysis output file.

**Usage**

```
wtarea(ideal=c(160,170))
wtflags(weight=0,cutoff=0)
wtIgnore.Filter
```

**Arguments**

ideal	numeric vector giving the ideal area or range of areas for a spot in pixels
weight	weight to be given to flagged spots
cutoff	cutoff value for Flags below which spots will be downweighted

**Details**

These functions can be passed as an argument to `read.maimages` to construct quality weights as the microarray data is read in.

`wtarea` downweights unusually small or large spots and is designed for SPOT output. It gives weight 1 to spots which have areas in the ideal range, given in pixels, and linearly downweights spots which are smaller or larger than this range.

`wtflags` is designed for GenePix output and gives the specified weight to spots with Flags value less than the cutoff value. Choose `cutoff=0` to downweight all flagged spots. Choose `cutoff=-50` to downweight bad or absent spots or `cutoff=-75` to downweight only spots which have been manually flagged as bad.

`wtIgnore.Filter` is designed for QuantArray output and sets the weights equal to the column Ignore Filter produced by QuantArray. These weights are 0 for spots to be ignored and 1 otherwise.

**Value**

A function which takes a dataframe or matrix as argument and produces a numeric vector of weights between 0 and 1

**Author(s)**

Gordon Smyth

**See Also**

An overview of LIMMA functions for reading data is given in [03.ReadingData](#).

**Examples**

```
# Read in spot output files from current directory and give full weight to 165
# pixel spots. Note: for this example to run you must set fnames to the names
# of actual spot output files (data not provided).
## Not run:
RG <- read.maimages(fnames,source="spot",wt.fun=wtarea(165))
# Spot will be downweighted according to weights found in RG
MA <- normalizeWithinArrays(RG,layout)

## End(Not run)
```

---

rankSumTestWithCorrelation

*Two Sample Wilcoxon-Mann-Whitney Rank Sum Test Allowing For Correlation*

---

**Description**

A extension of the well-known rank-based test, but allowing for correlations between cases.

**Usage**

```
rankSumTestWithCorrelation(index, statistics, correlation=0, df=Inf)
```

**Arguments**

index	any index vector such that <code>statistics[index]</code> contains the values of the statistic for the test group.
statistics	numeric vector giving values of the test statistic.
correlation	numeric scalar, average correlation between cases in the test group. Cases in the second group are assumed independent of each other and other the first group.
df	degrees of freedom which the correlation has been estimated.

**Details**

This function implements a correlation-adjusted version of the Wilcoxon-Mann-Whitney test proposed by Wu and Smyth (2012). It tests whether the mean rank of statistics in the test group is greater or less than the mean rank of the remaining statistic values.

When the correlation (or variance inflation factor) is zero, the function performs the usual two-sample Wilcoxon-Mann-Whitney rank sum test. The Wilcoxon-Mann-Whitney test is implemented following the formulas given in Zar (1999) Section 8.10, including corrections for ties and for continuity.

The test allows for the possibility that cases in the test group may be more highly correlated on average than cases not in the group. When the correlation is non-zero, the variance of the rank-sum statistic is computed using a formula derived from equation (4.5) of Barry et al (2008). When the correlation is positive, the variance is increased and test will become more conservative.

**Value**

Numeric vector of length 2 containing the `left.tail` and `right.tail` p-values.

**Author(s)**

Gordon Smyth and Di Wu

**Examples**

```
stat <- rnorm(100)
index <- 1:10
stat[index] <- stat[1:10]+1

rankSumTestWithCorrelation(index, stat)
rankSumTestWithCorrelation(index, stat, correlation=0.1)

group <- rep(1,100)
group[index] <- 2
group <- factor(group)
wilcox.test(stat ~ group)
```

---

read.columns

*Read specified columns from a file*

---

**Description**

Reads specified columns from a file in table format and creates a data frame from it, with cases corresponding to lines and variables to fields in the file.

**Usage**

```
read.columns(file, required.col=NULL, text.to.search="", sep="\t", quote="\\"", skip=0,
             fill=TRUE, blank.lines.skip=TRUE, comment.char="", allowEscapes=FALSE, ...)
```

**Arguments**

<code>file</code>	the name of the file which the data are to be read from.
<code>required.col</code>	character vector of names of the required columns
<code>text.to.search</code>	character string. If any column names can be found in this string, those columns will also be read.
<code>sep</code>	the field separator character
<code>quote</code>	character string of characters to be treated as quote marks
<code>skip</code>	the number of lines of the data file to skip before beginning to read data.
<code>fill</code>	logical: if TRUE then in case the rows have unequal length, blank fields are implicitly added.
<code>blank.lines.skip</code>	logical: if TRUE blank lines in the input are ignored.
<code>comment.char</code>	character: a character vector of length one containing a single character or an empty string.
<code>allowEscapes</code>	logical. Should C-style escapes such as ‘\n’ be processed or read verbatim (the default)?
<code>...</code>	other arguments are passed to <code>read.table</code> , excluding the following which are reserved and cannot be set by the user: <code>header</code> , <code>col.names</code> , <code>check.names</code> and <code>colClasses</code> .

**Details**

This function is an interface to `read.table` in the base package. It uses `required.col` and `text.to.search` to set up the `colClasses` argument of `read.table`.

Note the following arguments of `read.table` are used by `read.columns` and therefore cannot be set by the user: `header`, `col.names`, `check.names` and `colClasses`.

This function is used by [read.maimages](#).

**Value**

A data frame (`data.frame`) containing a representation of the data in the file.

**Author(s)**

Gordon Smyth

An overview of LIMMA functions for reading data is given in [03.ReadingData](#).

---

read.idat	<i>Read Illumina expression data directly from IDAT files</i>
-----------	---

---

## Description

Read Illumina BeadArray data from IDAT and manifest (.bgx) files for gene expression platforms.

## Usage

```
read.idat(idatfiles, bgxfile, dateinfo = FALSE, annotation = "Symbol",
          tolerance = 0L, verbose = TRUE)
```

## Arguments

idatfiles	character vector specifying idat files to be read in.
bgxfile	character string specifying bead manifest file (.bgx) to be read in.
dateinfo	logical. Should date and software version information be read in?
annotation	character vector of annotation columns to be read from the manifest file.
tolerance	integer. The number of probe ID discrepancies allowed between the manifest and any of the IDAT files.
verbose	logical. Should progress messages are sent to standard output?

## Details

Illumina's BeadScan/iScan software outputs probe intensities in IDAT format (encrypted XML files) and uses probe information stored in a platform specific manifest file (.bgx). These files can be processed using the low-level functions `readIDAT` and `readBGX` from the `illuminaio` package (Smith et al. 2013).

The `read.idat` function provides a convenient way to read these files into R and to store them in an `EListRaw`-class object. The function serves a similar purpose to `read.ilmn`, which reads text files exported by Illumina's GenomeStudio software, but it reads the IDAT files directly without any need to convert them first to text.

The function reads information on control probes as well for regular probes. Probe types are indicated in the `Status` column of the `genes` component of the `EListRaw` object.

The `annotation` argument specifies probe annotation columns to be extracted from the manifest file. The manifest typically contains the following columns: "Species", "Source", "Search\_Key", "Transcript", "ILMN\_Gene", "Source\_Reference\_ID", "RefSeq\_ID", "Unigene\_ID", "Entrez\_Gene\_ID", "GI", "Accession", "Symbol", "Protein\_Product", "Probe\_Id", "Array\_Address\_Id", "Probe\_Type", "Probe\_Start", "Probe\_Sequence", "Chromosome", "Probe\_Chr\_Orientation", "Probe\_Coordinates", "Cytoband", "Definition", "Ontology\_Component", "Ontology\_Process", "Ontology\_Function", "Synonyms", "Obsolete\_Probe\_Id". Note that "Probe\_Id" and "Array\_Address\_Id" are always extracted and do not need to be included in the `annotation` argument.

If more than `tolerance` probes in the manifest cannot be found in an IDAT file then the function will return an error.

**Value**

An EListRaw object with the following components:

E	numeric matrix of raw intensities.
other\$NumBeads	numeric matrix of same dimensions as E giving number of beads used for each intensity value.
other\$STDEV	numeric matrix of same dimensions as E giving bead-level standard deviation or standard error for each intensity value.
genes	data.frame of probe annotation. This includes the Probe_Id and Array_Address_Id columns extracted from the manifest file, plus a Status column identifying control probes, plus any other columns specified by annotation.
targets	data.frame of sample information. This includes the IDAT file names plus other columns if dateinfo=TRUE.

**Author(s)**

Matt Ritchie

**References**

Smith ML, Baggerly KA, Bengtsson H, Ritchie ME, Hansen KD (2013). illuminaio: An open source IDAT parsing tool. *F1000 Research* 2, 264. <http://f1000research.com/articles/2-264/>

**See Also**

[read.ilmn](#) imports gene expression data output by GenomeStudio.

[neqc](#) performs normexp by control background correction, log transformation and quantile between-array normalization for Illumina expression data.

[propexpr](#) estimates the proportion of expressed probes in a microarray.

[detectionPValues](#) computes detection p-values from the negative controls.

**Examples**

```
## Not run:
idatfiles <- dir(pattern="idat")
bgxfile <- dir(pattern="bgx")
x <- read.idat(idatfiles, bgxfile)
x$other$Detection <- detectionPValues(x)
propexpr(data)
y <- neqc(data)

## End(Not run)
```

---

read.ilmn *Read Illumina Expression Data*

---

### Description

Read Illumina summary probe profile files and summary control probe profile files

### Usage

```
read.ilmn(files=NULL, ctrlfiles=NULL, path=NULL, ctrlpath=NULL, probeid="Probe",
          annotation=c("TargetID", "SYMBOL"), expr="AVG_Signal",
          other.columns="Detection", sep="\t", quote="", verbose=TRUE, ...)
```

### Arguments

files	character vector giving the names of the summary probe profile files.
ctrlfiles	character vector giving the names of the summary control probe profile files.
path	character string giving the directory containing the summary probe profile files. Default is the current working directory.
ctrlpath	character string giving the directory containing the summary control probe profile files. Default is the same directory as for the probe profile files.
probeid	character string giving the name of the probe identifier column.
annotation	character vector giving possible column names for probe annotation.
expr	character string giving a keyword identifying the expression intensity columns. Any input column with column name containing this key will be read as containing intensity values.
other.columns	character vector giving keywords sufficient to identify any extra data columns that should be read in, such as "Detection", "Avg_NBEADS", "BEAD_STDEV" etc. The default of <code>Detection</code> is usually sufficient to identify the columns containing detection p-values.
sep	the field separator character.
quote	character string of characters to be treated as quote marks.
verbose	logical, TRUE to report names of profile files being read.
...	any other parameters are passed on to <a href="#">read.columns</a> .

### Details

Illumina BeadStudio outputs probe intensities (regular probe intensities) and control probe intensities to summary probe profile files (containing regular probes) and summary control probe profile files, respectively. If both `files` and `ctrlfiles` are not NULL, this function will combine the data read from the two file types and save them to an [EListRaw-class](#) object. If one of them is NULL, then only the required data are read in.

Probe types are indicated in the `Status` column of genes, a component of the returned [EListRaw-class](#) object. There are totally seven types of control probes including negative, biotin, labeling, cy3\_hyb, housekeeping, high\_stringency\_hyb or low\_stringency\_hyb. Regular probes have the probe type regular. The `Status` column will not be created if `ctrlfiles` is NULL.

To read in columns other than `probeid`, `annotation` and `expr`, users needs to specify keywords in `other.columns`. One keyword corresponds to one type of columns. Examples of keywords are "Detection", "Avg\_NBEADS", "BEAD\_STDEV" etc.

**Value**

An [EListRaw-class](#) object with the following components:

E	numeric matrix of intensities.
genes	data.frame of probe annotation. Contains any columns specified by annotation that are found in the input files.
other	a list of matrices corresponding to any other . columns found in the input files.

**Author(s)**

Wei Shi and Gordon K Smyth

**See Also**

[read.ilmn.targets](#) reads in Illumina expression data using the file information extracted from a target data frame which is often created by the [readTargets](#) function.

[neqc](#) performs normexp by control background correction, log transformation and quantile between-array normalization for Illumina expression data.

[normexp.fit.control](#) estimates the parameters of the normal+exponential convolution model with the help of negative control probes.

[propexpr](#) estimates the proportion of expressed probes in a microarray.

**Examples**

```
## Not run:
x <- read.ilmn(files="sample probe profile.txt",
              ctrlfiles="control probe profile.txt")

## End(Not run)
# See neqc and beadCountWeights for other examples using read.ilmn
```

---

read.ilmn.targets      *Read Illumina Data from a Target Dataframe*

---

**Description**

Read Illumina data from a target dataframe

**Usage**

```
read.ilmn.targets(targets, ...)
```

**Arguments**

targets      data frame including names of profile files.  
 ...          any other parameters are passed on to [read.ilmn](#).

**Details**

targets is often created by calling the function `readTargets`. Rows in targets are arrays and columns contain related array or RNA sample information.

At least one of the two columns called files and/or ctrlfiles should be present in targets, which includes names of summary probe profile files and names of summary control probe profile files respectively. This function calls `read.ilmn` to read in the data.

**Value**

An `EListRaw`-class object. See return value of the function `read.ilmn` for details.

**Author(s)**

Wei Shi

`read.ilmn`

---

read.maimages

*Read RGList or EListRaw from Image Analysis Output Files*

---

**Description**

Reads an RGList from a set of two-color microarray image analysis output files, or an EListRaw from a set of one-color files.

**Usage**

```
read.maimages(files=NULL, source="generic", path=NULL, ext=NULL, names=NULL,
              columns=NULL, other.columns=NULL, annotation=NULL, green.only=FALSE,
              wt.fun=NULL, verbose=TRUE, sep="\t", quote=NULL, ...)
read.imagene(files, path=NULL, ext=NULL, names=NULL, columns=NULL, other.columns=NULL,
             wt.fun=NULL, verbose=TRUE, sep="\t", quote="", ...)
```

**Arguments**

files	character vector giving the names of the files containing image analysis output or, for Imagene data, a character matrix of names of files. Alternatively, it can be a data.frame containing a column called FileName. If omitted, then all files with extension ext in the specified directory will be read in alphabetical order.
source	character string specifying the image analysis program which produced the output files. Choices are "generic", "agilent", "agilent.median", "agilent.mean", "arrayvision", "arrayvision.ARM", "arrayvision.MTM", "bluefuse", "genepix", "genepix.custom", "genepix.median", "imagene", "imagene9", "quantarray", "scanarrayexpress", "smd.old", "smd", "spot" or "spot.close.open".
path	character string giving the directory containing the files. The default is the current working directory.
ext	character string giving optional extension to be added to each file name

names	character vector of unique names to be associated with each array as column name. Can be supplied as files\$Label if files is a data.frame. Defaults to removeExt(files).
columns	list, or named character vector. For two color data, this should have fields R, G, Rb and Gb giving the column names to be used for red and green foreground and background or, in the case of Imagen data, a list with fields f and b. For single channel data, the fields are usually E and Eb. This argument is optional if source is specified, otherwise it is required.
other.columns	character vector of names of other columns to be read containing spot-specific information
annotation	character vector of names of columns containing annotation information about the probes
green.only	logical, for use with source, should the green (Cy3) channel only be read, or are both red and green required?
wt.fun	function to calculate spot quality weights
verbose	logical, TRUE to report each time a file is read
sep	the field separator character
quote	character string of characters to be treated as quote marks
...	any other arguments are passed to read.table

## Details

These are the main data input functions for the LIMMA package. `read.maimages` reads either single channel or two-color microarray intensity data from text files. `read.imagen` is specifically for two-color Imagen intensity data created by Imagen versions 1 through 8, and is called by `read.maimages` to read such data.

`read.maimages` is designed to read data from any microarray platform except for Illumina Bead-Chips, which are read by `read.ilmn`, and Affymetrix GeneChip data, which is best read and pre-processed by specialist packages designed for that platform.

`read.maimages` extracts the foreground and background intensities from a series of files, produced by an image analysis program, and assembles them into the components of one list. The image analysis programs Agilent Feature Extraction, ArrayVision, BlueFuse, GenePix, Imagen, QuantArray (Version 3 or later), Stanford Microarray Database (SMD) and SPOT are supported explicitly. Almost all these programs write the intensity data for each microarray to one file. The exception is Imagen, early versions of which wrote the red and green channels of each microarray to different files. Data from some other image analysis programs not mentioned above can be read if the appropriate column names containing the foreground and background intensities are specified using the `columns` argument. (Reading custom columns will work provided the column names are unique and there are no rows in the file after the last line of data. Header lines are ok.)

For Agilent files, two possible foreground estimators are supported: `source="agilent.median"` use median foreground while `source="agilent.mean"` uses mean foreground. Background estimates are always medians. The use of `source="agilent"` defaults to `"agilent.median"`. Note that this behavior is new from 9 March 2012. Previously, in `limma` 3.11.16 or earlier, `"agilent"` had the same meaning as `"agilent.mean"`.

For GenePix files, two possible foreground estimators are supported as well as custom background: `source="genepix.median"` uses the median foreground estimates while `source="genepix.mean"` uses mean foreground estimates. The use of `source="genepix"` defaults to `"genepix.mean"`. Background estimates are always medians unless `source="genepix.custom"` is specified. GenePix 6.0 and later supply some custom background options, notably morphological background. If the

GPR files have been written using a custom background, then `source="genepix.custom"` will cause it to be read and used.

For SPOT files, two possible background estimators are supported: `source="spot"` uses background intensities estimated from the morphological opening algorithm. If `source="spot.close.open"` then background intensities are estimated from morphological closing followed by opening.

ArrayVision reports spot intensities in a number of different ways. `read.maimages` caters for ArrayVision's Artifact-removed (ARM) density values using `source="arrayvision.ARM"` or for Median-based Trimmed Mean (MTM) density values with `"arrayvision.MTM"`. ArrayVision users may find it useful to read the top two lines of their data file to check which version of density values they have.

SMD data should consist of raw data files from the database, in tab-delimited text form. There are two possible sets of column names depending on whether the data was entered into the database before or after September 2003. `source="smd.old"` indicates that column headings in use prior to September 2003 should be used.

Intensity data from ImaGene versions 1 to 8 (`source="imagine"`) is different from other image analysis programs in that the read and green channels were written to separate files. `read.maimages` handles the special behaviour of the early ImaGene versions by requiring that the argument `files` should be a matrix with two columns instead of a vector. The first column should contain the names of the files containing green channel (cy3) data and the second column should contain names of files containing red channel (cy5) data. Alternately, files can be entered as a vector of even length instead of a matrix. In that case, each consecutive pair of file names is assumed to contain the green (cy3) and red (cy5) intensities respectively from the same array. The function `read.imagine` is called by `read.maimages` when `source="imagine"`, so `read.imagine` does not need to be called directly by users.

ImaGene version~9 (`source="imagine9"`) reverts to the same behavior as the other image analysis programs. For ImaGene~9, `files` is a vector of length equal to the number of microarrays, same as for other image analysis programs.

Spot quality weights may be extracted from the image analysis files using a weight function `wt.fun`. `wt.fun` may be any user-supplied function which accepts a `data.frame` argument and returns a vector of non-negative weights. The columns of the `data.frame` are as in the image analysis output files. There is one restriction, which is that the column names should be referred to in full form in the weight function, i.e., do not rely on name expansion for partial matches when referring to the names of the columns. See [QualityWeights](#) for suggested weight functions.

The argument `other.columns` allows arbitrary columns of the image analysis output files to be preserved in the data object. These become matrices in the component `other` component. For ImaGene data, the other column headings should be prefixed with "R " or "G " as appropriate.

## Value

For one-color data, an [EListRaw](#) object. For two-color data, an [RGList](#) object containing the components

R	matrix containing the red channel foreground intensities for each spot for each array.
Rb	matrix containing the red channel background intensities for each spot for each array.
G	matrix containing the green channel foreground intensities for each spot for each array.
Gb	matrix containing the green channel background intensities for each spot for each array.

weights	spot quality weights, if wt.fun is given
other	list containing matrices corresponding to other.columns if given
genes	data frame containing annotation information about the probes, for example gene names and IDs and spatial positions on the array, currently set only if source is "agilent", "genepix" or source="imagine" or if the annotation argument is set
targets	data frame with column FileName giving the names of the files read. If files was a data.frame on input, then the whole data.frame is stored here on output.
source	character string giving the image analysis program name
printer	list of class <code>PrintLayout</code> , currently set only if source="imagine"

### Warnings

All image analysis files being read are assumed to contain data for the same genelists in the same order. No checking is done to confirm that this is true. Probe annotation information is read from the first file only.

### Author(s)

Gordon Smyth, with speed improvements suggested by Marcus Davy

### References

### See Also

read.maimages uses `read.columns` for efficient reading of text files. As far as possible, it is has similar behavior to `read.table` in the base package.

`read.ilmn` reads probe or gene summary profile files from Illumina BeadChips.

An overview of LIMMA functions for reading data is given in [03.ReadingData](#).

### Examples

```
# Read all .gpr files from current working directory
# and give weight 0.1 to spots with negative flags

## Not run: files <- dir(pattern="*\\.gpr$")
RG <- read.maimages(files,"genepix",wt.fun=wtflags(0.1))
## End(Not run)

# Read all .spot files from current working director and down-weight
# spots smaller or larger than 150 pixels

## Not run: files <- dir(pattern="*\\.spot$")
RG <- read.maimages(files,"spot",wt.fun=wtarea(150))
## End(Not run)
```

---

readGAL	<i>Read a GAL file</i>
---------	------------------------

---

**Description**

Read a GenePix Array List (GAL) file into a dataframe.

**Usage**

```
readGAL(galfile=NULL, path=NULL, header=TRUE, sep="\t", quote="", skip=NULL, as.is=TRUE, ...)
```

**Arguments**

galfile	character string giving the name of the GAL file. If NULL then a file with extension .gal is found in the directory specified by path.
path	character string giving the directory containing the files. If NULL then assumed to be the current working directory.
header	logical variable, if TRUE then the first line after skip is assumed to contain column headings. If FALSE then a value should specified for skip.
sep	the field separator character
quote	the set of quoting characters
skip	number of lines of the GAL file to skip before reading data. If NULL then this number is determined by searching the file for column headings.
as.is	logical variable, if TRUE then read in character columns as vectors rather than factors.
...	any other arguments are passed to read.table

**Details**

A GAL file is a list of genes IDs and associated information produced by an Axon microarray scanner. Apart from header information, the file must contain data columns labeled Block, Column, Row and ID. A Name column is usually included as well. Other columns are optional. See the Axon URL below for a detaile description of the GAL file format.

This function reads in the data columns with a minimum of user information. In most cases the function can be used without specifying any of the arguments.

**Value**

A data frame with columns

Block	numeric vector containing the print tip indices
Column	numeric vector containing the spot columns
Row	numeric vector containing the spot rows
ID	character vector, for factor if as.is=FALSE, containing gene library identifiers
Name	character vector, for factor if as.is=FALSE, containing gene names

The data frame will be sorted so that Column is the fastest moving index, then Row, then Block.

**See Also**

read.Galfile in the marray package.

An overview of LIMMA functions for reading data is given in [03.ReadingData](#).

**Examples**

```
# readGAL()
# will read in the first GAL file (with suffix ".gal")
# found in the current working directory
```

---

readHeader

*Read Header Information from Microarray Raw Data File*

---

**Description**

Read the header information from a microarray raw data file, as output from an image analysis software program such as GenePix. These functions are used internally by read.maimages and are not usually called directly by users.

**Usage**

```
readGenericHeader(file, columns, sep="\t")
readGPRHeader(file)
readSMDHeader(file)
```

**Arguments**

file	character string giving file name. If it does not contain an absolute path, the file name is relative to the current working directory.
columns	character vector specifying data column headings expected to be in file
sep	the character string separating column names

**Details**

Raw data files exported by image analysis programs include a number of header lines which contain information about the scanning process. This function extracts that information and locates the line where the intensity data begins. readGPRHeader is for GenePix output and readSMDHeader is for files from the Stanford Microarray Database (SMD). readGenericHeader finds the line in the file on which the data begins by searching for specified column headings.

**Value**

A list with components corresponds to lines of header information. A key component is `NHeaderRecords` which gives the number of lines in the file before the intensity data begins. All other components are character vectors.

**Author(s)**

Gordon Smyth

**References**

See [http://www.cryer.co.uk/file-types/a/atf/genepix\\_file\\_formats.htm](http://www.cryer.co.uk/file-types/a/atf/genepix_file_formats.htm) for GenePix formats.

---

readImaGeneHeader	<i>Read ImaGene Header Information</i>
-------------------	--

---

**Description**

Read the header information from an ImaGene image analysis output file. This function is used internally by `read.maimages` and is not usually called directly by users.

**Usage**

```
readImaGeneHeader(file)
```

**Arguments**

`file`                      character string giving file name or path

**Details**

The raw data files exported by the image analysis software ImaGene include a number of header lines which contain information about the printing and scanning processes. This function extracts that information and locates the line where the intensity data begins.

**Value**

A list containing information read from the header of the ImaGene file. Each Begin-End environment found in the file header will become a recursive list in the output object, with components corresponding to fields in the file. See the ImaGene documentation for further information. The output object will also contain a component `NHeaderRecords` giving the number of lines in the file before the intensity data begins.

**Author(s)**

Gordon Smyth

**References**<http://www.biodiscovery.com/software/imagene>**See Also**[read.imagene](#)An overview of LIMMA functions to read data is given in [03.ReadingData](#).**Examples**

```
## Not run:
h <- readImaGeneHeader("myImaGeneFile.txt")
names(h)
h$headerRecords
h[["Field Dimensions"]]

## End(Not run)
```

readSpotTypes

*Read Spot Types File***Description**

Read a table giving regular expressions to identify different types of spots in the gene-dataframe.

**Usage**

```
readSpotTypes(file="SpotTypes.txt", path=NULL, sep="\t", check.names=FALSE, ...)
```

**Arguments**

file	character string giving the name of the file specifying the spot types.
path	character string giving the directory containing the file. Can be omitted if the file is in the current working irectory.
sep	the field separator character
check.names	logical, if FALSE column names will not be converted to valid variable names, for example spaces in column names will not be left as is
...	any other arguments are passed to read.table

**Details**

The file is a text file with rows corresponding to types of spots and the following columns: SpotType gives the name for the spot type, ID is a regular expression matching the ID column, Name is a regular expression matching the Name column, and Color is the R name for the color to be associated with this type.

**Value**

A data frame with columns

SpotType	character vector giving names of the spot types
ID	character vector giving regular expressions
Name	character vector giving regular expressions
Color	character vector giving names of colors

**Author(s)**

Gordon Smyth following idea of James Wettenhall

**See Also**

An overview of LIMMA functions for reading data is given in [03.ReadingData](#).

---

readTargets	<i>Read Targets File</i>
-------------	--------------------------

---

**Description**

Read targets file for a microarray experiment into a dataframe.

**Usage**

```
readTargets(file="Targets.txt", path=NULL, sep="\t", row.names=NULL, quote="", ...)
```

**Arguments**

file	character string giving the name of the targets file.
path	character string giving the directory containing the file. Can be omitted if the file is in the current working irectory.
sep	field separator character
row.names	character string giving the name of a column from which to obtain row names
quote	the set of quoting characters
...	other arguments are passed to <a href="#">read.table</a>

**Details**

The targets file is a text file containing information about the RNA samples used as targets in the microarray experiment. Rows correspond to arrays and columns to covariates associated with the targets. For a two-color experiment, the targets file will normally include columns labelled Cy3 and Cy5 or similar specifying which RNA samples are hybridized to each channel of each array. Other columns may contain any other covariate information associated with the arrays or targets used in the experiment.

If row.names is non-null and there is a column by that name with unique values, then those values will be used as row names for the dataframe. If row.names is null, then the column Label will be used if such exists or, failing that, the column FileName.

See the Limma User's Guide for examples of this function.

**Value**

A dataframe. Character columns are not converted into factors.

**Author(s)**

Gordon Smyth

---

removeBatchEffect	<i>Remove Batch Effect</i>
-------------------	----------------------------

---

**Description**

Remove batch effects from expression data.

**Usage**

```
removeBatchEffect(x, batch=NULL, batch2=NULL, covariates=NULL,  
                  design=matrix(1,ncol(x),1), ...)
```

**Arguments**

x	numeric matrix, or any data object that can be processed by <a href="#">getEAWP</a> containing log-expression values for a series of samples. Rows correspond to probes and columns to samples.
batch	factor or vector indicating batches.
batch2	optional factor or vector indicating a second series of batches.
covariates	matrix or vector of numeric covariates to be adjusted for.
design	optional design matrix relating to treatment conditions to be preserved
...	other arguments are passed to <a href="#">lmFit</a> .

**Details**

This function is useful for removing batch effects, associated with hybridization time or other technical variables, prior to clustering or unsupervised analysis such as PCA, MDS or heatmaps. The design matrix is used to describe comparisons between the samples, for example treatment effects, which should not be removed. The function (in effect) fits a linear model to the data, including both batches and regular treatments, then removes the component due to the batch effects.

In most applications, only the first batch argument will be needed. This covers the situation where the data has been collected in a series of separate batches.

The batch2 argument is used when there is a second series of batch effects, independent of the first series. For example, batch might correspond to time of data collection while batch2 might correspond to operator or some other change in operating characteristics. If batch2 is included, then the effects of batch and batch2 are assumed to be additive.

The `covariates` argument allows correction for one or more continuous numeric effects, similar to the analysis of covariance method in statistics. If `covariates` contains more than one column, then the columns are assumed to have additive effects.

The data object `x` can be of any class for which `lmFit` works. If `x` contains weights, then these will be used in estimating the batch effects.

### Value

A numeric matrix of log-expression values with batch and covariate effects removed.

### Note

This function is not intended to be used prior to linear modelling. For linear modelling, it is better to include the batch factors in the linear model.

### Author(s)

Gordon Smyth and Carolyn de Graaf

### See Also

### Examples

```
y <- matrix(rnorm(10*9),10,9)
y[,1:3] <- y[,1:3] + 5
batch <- c("A","A","A","B","B","B","C","C","C")
y2 <- removeBatchEffect(y, batch)
par(mfrow=c(1,2))
boxplot(as.data.frame(y),main="Original")
boxplot(as.data.frame(y2),main="Batch corrected")
```

---

removeExt

*Remove Common Extension from File Names*

---

### Description

Finds and removes any common extension from a vector of file names.

### Usage

```
removeExt(x, sep=".")
```

### Arguments

<code>x</code>	character vector
<code>sep</code>	character string that separates the body of each character string from the extension.

**Details**

This function is used for simplifying file names, or any vector of character strings, when the strings all finish with the same suffix or extension. If the same extension is not shared by every element of `x`, then it is not removed from any element.

Note that `sep` is interpreted as a literal character string: it is not a regular expression.

**Value**

A character vector of the same length as `x` in which any common extension has been stripped off.

**Author(s)**

Gordon Smyth

**Examples**

```
x <- c("slide1.spot", "slide2.spot", "slide3.spot")
removeExt(x)
```

```
x <- c("Harry - a name from Harry Potter", "Hermione - a name from Harry Potter")
removeExt(x, sep=" - ")
```

---

residuals.MArrayLM     *Extract Residuals from MArrayLM Fit*

---

**Description**

This method extracts the residuals from all the probewise linear model fits and returns them in a matrix.

**Usage**

```
## S3 method for class 'MArrayLM'
residuals(object, y, ...)
```

**Arguments**

<code>object</code>	a fitted model object inheriting from class <code>MarrayLM</code> .
<code>y</code>	a data object containing the response data used to compute the fit. This can be of any class for which <code>as.matrix</code> is defined, including <code>MAList</code> , <code>ExpressionSet</code> , <code>marrayNorm</code> etc.
<code>...</code>	other arguments are not used

**Value**

Numeric matrix of residuals.

**See Also**

[residuals](#).

---

RGList-class

*Red, Green Intensity List - class*

---

**Description**

A list-based S4 class for storing red and green channel foreground and background intensities for a batch of spotted microarrays. RGList objects are normally created by [read.maimages](#).

**Slots/List Components**

RGList objects can be created by `new("RGList",RG)` where RG is a list. Objects of this class contains no slots (other than `.Data`), but objects should contain the following list components:

- R numeric matrix containing the red (cy5) foreground intensities. Rows correspond to spots and columns to arrays.
- G numeric matrix containing the green (cy3) foreground intensities. Rows correspond to spots and columns to arrays.

Optional components include

- Rb numeric matrix containing the red (cy5) background intensities
- Gb numeric matrix containing the green (cy3) background intensities
- weights numeric matrix of same dimension as R containing relative spot quality weights. Elements should be non-negative
- other list containing other matrices, all of the same dimensions as R and G.
- genes data.frame containing probe information. Should have one row for each spot. May have any number of columns
- targets data.frame containing information on the target RNA samples. Rows correspond to arrays. May have any number of columns
- printer list containing information on the process used to print the spots on the arrays. See [PrintLayout](#).

Valid RGList objects may contain other optional components, but all probe or array information should be contained in the above components.

**Methods**

This class inherits directly from class `list` so any operation appropriate for lists will work on objects of this class. In addition, RGList objects can be [subsetted](#), [combined](#) and [merged](#). RGList objects will return dimensions and hence functions such as `dim`, `nrow` and `ncol` are defined. RGLists also inherit a `show` method from the virtual class `LargeDataObject`, which means that RGLists will print in a compact way.

RGList objects can be converted to `exprSet2` objects by `as(RG, "exprSet2")`.

Other functions in LIMMA which operate on RGList objects include [normalizeBetweenArrays](#), [normalizeForPrintorder](#), [normalizeWithinArrays](#).

**Author(s)**

Gordon Smyth

**See Also**

[02.Classes](#) gives an overview of all the classes defined by this package.

marrayRaw is the corresponding class in the marray package.

---

roast

*Rotation Gene Set Tests*

---

## Description

Rotation gene set testing for linear models.

## Usage

```
## Default S3 method:
roast(y, index = NULL, design = NULL, contrast = ncol(design), geneid = NULL,
      set.statistic = "mean", gene.weights = NULL, var.prior = NULL, df.prior = NULL,
      nrot = 999, approx.zscore = TRUE, ...)

## Default S3 method:
mroast(y, index = NULL, design = NULL, contrast = ncol(design), geneid = NULL,
       set.statistic = "mean", gene.weights = NULL, var.prior = NULL, df.prior = NULL,
       nrot = 999, approx.zscore = TRUE, adjust.method = "BH",
       midp = TRUE, sort = "directional", ...)

## Default S3 method:
fry(y, index = NULL, design = NULL, contrast = ncol(design), geneid = NULL,
   standardize = "posterior.sd", sort = "directional", ...)
```

## Arguments

<code>y</code>	numeric matrix giving log-expression or log-ratio values for a series of microarrays, or any object that can be coerced to a matrix including <code>ExpressionSet</code> , <code>MAList</code> , <code>EList</code> or <code>PLMSet</code> objects. Rows correspond to probes and columns to samples. If either <code>var.prior</code> or <code>df.prior</code> are <code>NULL</code> , then <code>y</code> should contain values for all genes on the arrays. If both prior parameters are given, then only <code>y</code> values for the test set are required.
<code>index</code>	index vector specifying which rows (probes) of <code>y</code> are in the test set. Can be a vector of integer indices, or a logical vector of length <code>nrow(y)</code> , or a vector of gene IDs corresponding to entries in <code>geneid</code> . Alternatively it can be a <code>data.frame</code> with the first column containing the index vector and the second column containing directional gene contribution weights. For <code>mroast</code> or <code>fry</code> , <code>index</code> is a list of index vectors or a list of <code>data.frames</code> .
<code>design</code>	design matrix
<code>contrast</code>	contrast for which the test is required. Can be an integer specifying a column of <code>design</code> , or the name of a column of <code>design</code> , or a numeric contrast vector of length equal to the number of columns of <code>design</code> .
<code>geneid</code>	gene identifiers corresponding to the rows of <code>y</code> . Can be either a vector of length <code>nrow(y)</code> or the name of the column of <code>y\$genes</code> containing the gene identifiers. Defaults to <code>rownames(y)</code> .
<code>set.statistic</code>	summary set statistic. Possibilities are "mean", "floormean", "mean50" or "msq".
<code>gene.weights</code>	numeric vector of directional (positive or negative) contribution weights specifying the size and direction of the contribution of each probe to the gene set statistics. For <code>mroast</code> , this vector must have length equal to <code>nrow(y)</code> . For <code>roast</code> , can be of length <code>nrow(y)</code> or of length equal to the number of genes in the test set.

<code>var.prior</code>	prior value for residual variances. If not provided, this is estimated from all the data using <code>squeezeVar</code> .
<code>df.prior</code>	prior degrees of freedom for residual variances. If not provided, this is estimated using <code>squeezeVar</code> .
<code>nrot</code>	number of rotations used to compute the p-values.
<code>approx.zscore</code>	logical, if TRUE then a fast approximation is used to convert t-statistics into z-scores prior to computing set statistics. If FALSE, z-scores will be exact.
<code>adjust.method</code>	method used to adjust the p-values for multiple testing. See <a href="#">p.adjust</a> for possible values.
<code>midp</code>	logical, should mid-p-values be used in instead of ordinary p-values when adjusting for multiple testing?
<code>sort</code>	character, whether to sort output table by directional p-value ("directional"), non-directional p-value ("mixed"), or not at all ("none").
<code>standardize</code>	how to standardize for unequal probewise variances. Possibilities are "residual.sd", "posterior.sd" or "none".
<code>...</code>	any argument that would be suitable for <a href="#">lmFit</a> or <a href="#">eBayes</a> can be included.

## Details

These functions implement the ROAST gene set tests proposed by Wu et al (2010). They perform *self-contained* gene set tests in the sense defined by Goeman and Buhlmann (2007). For *competitive* gene set tests, see [camera](#). For a gene set enrichment analysis style analysis using a database of gene sets, see [romer](#).

`roast` and `mroast` test whether any of the genes in the set are differentially expressed. They can be used for any microarray experiment that can be represented by a linear model. The design matrix for the experiment is specified as for the [lmFit](#) function, and the contrast of interest is specified as for the [contrasts.fit](#) function. This allows users to focus on differential expression for any coefficient or contrast in a linear model. If `contrast` is not specified, then the last coefficient in the linear model will be tested.

The argument `index` is often made using [ids2indices](#) but does not have to be. Each set to be tested is represented by a vector of row numbers or a vector of gene IDs. Gene IDs should correspond to either the rownames of `y` or the entries of `geneid`.

The argument `gene.weights` allows directional contribution weights to be set for individual genes in the set. This is often useful, because it allows each gene to be flagged as to its direction and magnitude of change based on prior experimentation. A typical use is to make the `gene.weights` 1 or -1 depending on whether the gene is up or down-regulated in the pathway under consideration. Probes with directional weights of opposite signs are expected to have expression changes in opposite directions. If there are multiple sets to be tested, then set-specific gene weights can be included as part of the `index`. If any of the entries of `index` are `data.frames`, then the second column will be assumed to be gene contribution weights. All three functions (`roast`, `mroast` and `fry`) support set-specific gene contribution weights as part of an `index data.frame`.

Note that the contribution weights set by `gene.weights` are different in nature and purpose to the precision weights set by the `weights` argument to [lmFit](#). `gene.weights` control the contribution of each gene to the formation of the gene set statistics, and can be positive or negative. `weights` indicate the precision of the expression measurements and should be positive. The `weights` are used to construct genewise test statistics whereas `gene.weights` are used to combine the genewise test statistics.

The arguments `df.prior` and `var.prior` have the same meaning as in the output of the [eBayes](#) function. If these arguments are not supplied, then they are estimated exactly as is done by [eBayes](#).

The gene set statistics "mean", "floormean", "mean50" and msq are defined by Wu et al (2010). The different gene set statistics have different sensitivities to small number of genes. If `set.statistic="mean"` then the set will be statistically significant only when the majority of the genes are differentially expressed. "floormean" and "mean50" will detect as few as 25% differentially expressed. "msq" is sensitive to even smaller proportions of differentially expressed genes, if the effects are reasonably large.

The output gives p-values three possible alternative hypotheses, "Up" to test whether the genes in the set tend to be up-regulated, with positive t-statistics, "Down" to test whether the genes in the set tend to be down-regulated, with negative t-statistics, and "Mixed" to test whether the genes in the set tend to be differentially expressed, without regard for direction.

roast estimates p-values by simulation, specifically by random rotations of the orthogonalized residuals (Langsrud, 2005), so p-values will vary slightly from run to run. To get more precise p-values, increase the number of rotations `nrot`. The p-value is computed as  $(b+1)/(nrot+1)$  where `b` is the number of rotations giving a more extreme statistic than that observed (Phipson and Smyth, 2010). This means that the smallest possible p-value is  $1/(nrot+1)$ .

mroast does roast tests for multiple sets, including adjustment for multiple testing. By default, mroast reports ordinary p-values but uses mid-p-values (Routledge, 1994) at the multiple testing stage. Mid-p-values are probably a good choice when using false discovery rates (`adjust.method="BH"`) but not when controlling the family-wise type I error rate (`adjust.method="holm"`).

fry is a fast approximation to mroast. In the special case that `df.prior` is large and `set.statistic="mean"`, fry gives the same result as mroast with an infinite number of rotations. In other circumstances, when genes have different variances, fry uses a standardization strategy to approximate the mroast results. Using fry may be advisable when performing tests for a large number of sets, because it is fast and because the fry p-values are not limited by the number of rotations performed.

## Value

roast produces an object of class "Roast". This consists of a list with the following components:

<code>p.value</code>	data.frame with columns <code>Active.Prop</code> and <code>P.Value</code> , giving the proportion of genes in the set contributing materially to significance and estimated p-values, respectively. Rows correspond to the alternative hypotheses Down, Up, UpOrDown (two-sided) and Mixed.
<code>var.prior</code>	prior value for residual variances.
<code>df.prior</code>	prior degrees of freedom for residual variances.

mroast produces a data.frame with a row for each set and the following columns:

<code>NGenes</code>	number of genes in set
<code>PropDown</code>	proportion of genes in set with $z < -\sqrt{2}$
<code>PropUp</code>	proportion of genes in set with $z > \sqrt{2}$
<code>Direction</code>	direction of change, "Up" or "Down"
<code>PValue</code>	two-sided directional p-value
<code>FDR</code>	two-sided directional false discovery rate
<code>PValue.Mixed</code>	non-directional p-value
<code>FDR.Mixed</code>	non-directional false discovery rate

fry produces the same output format as mroast but without the columns `PropDown` and `PropUp`.

**Note**

The default setting for the set statistic was changed in limma 3.5.9 (3 June 2010) from "msq" to "mean".

See [10.GeneSetTests](#) for a description of other functions used for gene set testing.

**Examples**

```
y <- matrix(rnorm(100*4),100,4)
design <- cbind(Intercept=1,Group=c(0,0,1,1))

# First set of 5 genes contains 3 that are genuinely differentially expressed
index1 <- 1:5
y[index1,3:4] <- y[index1,3:4]+3

# Second set of 5 genes contains none that are DE
index2 <- 6:10

roast(y,index1,design,contrast=2)
fry(y,list(set1=index1,set2=index2),design,contrast=2)
```

**Description**

Gene set enrichment analysis for linear models using rotation tests (ROtation testing using MEan Ranks).

**Usage**

```
## Default S3 method:
romer(y, index, design = NULL, contrast = ncol(design),
      array.weights = NULL, block = NULL, correlation,
      set.statistic = "mean", nrot = 9999, shrink.resid = TRUE, ...)
```

**Arguments**

<code>y</code>	numeric matrix giving log-expression values.
<code>index</code>	list of indices specifying the rows of <code>y</code> in the gene sets. The list can be made using <code>ids2indices</code> .
<code>design</code>	design matrix.
<code>contrast</code>	contrast for which the test is required. Can be an integer specifying a column of <code>design</code> , or else a contrast vector of length equal to the number of columns of <code>design</code> .
<code>array.weights</code>	optional numeric vector of array weights.
<code>block</code>	optional vector of blocks.
<code>correlation</code>	correlation between blocks.
<code>set.statistic</code>	statistic used to summarize the gene ranks for each set. Possible values are "mean", "floormean" or "mean50".
<code>nrot</code>	number of rotations used to estimate the p-values.
<code>shrink.resid</code>	logical, should the residuals be shrunk to remove systematics effects before rotation.
<code>...</code>	other arguments not currently used.

**Details**

This function implements the ROMER procedure described by Majewski et al (2010) and Ritchie et al (2015). `romer` tests a hypothesis similar to that of Gene Set Enrichment Analysis (GSEA) (Subramanian et al, 2005) but is designed for use with linear models. Like GSEA, it is designed for use with a database of gene sets. Like GSEA, it is a competitive test in that the different gene sets are pitted against one another. Instead of permutation, it uses rotation, a parametric resampling method suitable for linear models (Langsrud, 2005; Wu et al, 2010). `romer` can be used with any linear model with some level of replication.

In the output, p-values are given for each set for three possible alternative hypotheses. The alternative "up" means the genes in the set tend to be up-regulated, with positive t-statistics. The alternative "down" means the genes in the set tend to be down-regulated, with negative t-statistics. The alternative "mixed" test whether the genes in the set tend to be differentially expressed, without regard for direction. In this case, the test will be significant if the set contains mostly large test statistics, even if some are positive and some are negative. The first two alternatives are appropriate if you have a prior expectation that all the genes in the set will react in the same direction. The "mixed" alternative is appropriate if you know only that the genes are involved in the relevant pathways, without knowing the direction of effect for each gene.

Note that `romer` estimates p-values by simulation, specifically by random rotations of the orthogonalized residuals (called effects in R). This means that the p-values will vary slightly from run to run. To get more precise p-values, increase the number of rotations `nrot`. By default, the orthogonalized residual corresponding to the contrast being tested is shrunk have the same expected squared size as a null residual.

The argument `set.statistic` controls the way that t-statistics are summarized to form a summary test statistic for each set. In all cases, genes are ranked by moderated t-statistic. If `set.statistic="mean"`, the mean-rank of the genes in each set is the summary statistic. If `set.statistic="floormean"` then negative t-statistics are put to zero before ranking for the up test, and vice versa for the down test. This improves the power for detecting genes with a subset of responding genes. If `set.statistic="mean50"`, the mean of the top 50% ranks in each set is the summary statistic. This statistic performs well in practice but is slightly slower to compute. See Wu et al (2010) for discussion of these set statistics.

### Value

Numeric matrix giving p-values and the number of matched genes in each gene set. Rows correspond to gene sets. There are four columns giving the number of genes in the set and p-values for the alternative hypotheses mixed, up or down.

selectModel                      *Select Appropriate Linear Model*

---

### Description

Select the best fitting linear model for each gene by minimizing an information criterion.

### Usage

```
selectModel(y, designlist, criterion="aic", df.prior=0, s2.prior=NULL, s2.true=NULL, ...)
```

### Arguments

y	a matrix-like data object, containing log-ratios or log-values of expression for a series of microarrays. Any object class which can be coerced to matrix is acceptable including numeric, matrix, MAList, marrayNorm, ExpressionSet or PLMset.
designlist	list of design matrices
criterion	information criterion to be used for model selection, "aic", "bic" or "mallowscp".
df.prior	prior degrees of freedom for residual variances. See <a href="#">squeezeVar</a>
s2.prior	prior value for residual variances, to be used if df.prior>0.
s2.true	numeric vector of true variances, to be used if criterion="mallowscp".
...	other optional arguments to be passed to lmFit

### Details

This function chooses, for each probe, the best fitting model out of a set of alternative models represented by a list of design matrices. Selection is by Akaike's Information Criterion (AIC), Bayesian Information Criterion (BIC) or by Mallow's Cp.

The criteria have been generalized slightly to accommodate an information prior on the variances represented by s2.prior and df.prior or by s2.post. Suitable values for these parameters can be estimated using [squeezeVar](#).

### Value

List with components	
IC	matrix of information criterion scores, rows for probes and columns for models
pref	factor indicating the model with best (lowest) information criterion score

### Author(s)

Alicia Oshlack and Gordon Smyth

B <- c(0,1,0,1,1)
designlist <- list(
  None=cbind(Int=c(1,1,1,1,1)),
  A=cbind(Int=1,A=A),
  B=cbind(Int=1,B=B),
  Both=cbind(Int=1,AB=A*B),
  Add=cbind(Int=1,A=A,B=B),
  Full=cbind(Int=1,A=A,B=B,AB=A*B)
)
out <- selectModel(y,designlist)
table(out$pref)

```

squeezeVar

*Squeeze Sample Variances***Description**

Squeeze a set of sample variances together by computing empirical Bayes posterior means.

**Usage**

```
squeezeVar(var, df, covariate=NULL, robust=FALSE, winsor.tail.p=c(0.05,0.1))
```

**Arguments**

var	numeric vector of independent sample variances.
df	numeric vector of degrees of freedom for the sample variances.
covariate	if non-NULL, var.prior will depend on this numeric covariate. Otherwise, var.prior is constant.
robust	logical, should the estimation of df.prior and var.prior be robustified against outlier sample variances?
winsor.tail.p	numeric vector of length 1 or 2, giving left and right tail proportions of x to Winsorize. Used only when robust=TRUE.

**Details**

This function implements an empirical Bayes algorithm proposed by Smyth (2004).

A conjugate Bayesian hierarchical model is assumed for a set of sample variances. The hyperparameters are estimated by fitting a scaled F-distribution to the sample variances. The function returns the posterior variances and the estimated hyperparameters.

Specifically, the sample variances var are assumed to follow scaled chi-squared distributions, conditional on the true variances, and an scaled inverse chi-squared prior is assumed for the true variances. The scale and degrees of freedom of this prior distribution are estimated from the values of var.

The effect of this function is to squeeze the variances towards a common value, or to a global trend if a covariate is provided. The squeezed variances have a smaller expected mean square error to the true variances than do the sample variances themselves.

If covariate is non-null, then the scale parameter of the prior distribution is assumed to depend on the covariate. If the covariate is average log-expression, then the effect is an intensity-dependent trend similar to that in Sartor et al (2006).

robust=TRUE implements the robust empirical Bayes procedure of Phipson et al (2016) which allows some of the var values to be outliers.

### Value

A list with components

var.post	numeric vector of posterior variances.
var.prior	location of prior distribution. A vector if covariate is non-NULL, otherwise a scalar.
df.prior	degrees of freedom of prior distribution. A vector if robust=TRUE, otherwise a scalar.

### Note

This function is called by eBayes, but beware a possible confusion with the output from that function. The values var.prior and var.post output by squeezeVar correspond to the quantities s2.prior and s2.post output by eBayes, whereas var.prior output by eBayes relates to a different parameter.

strsplit2	<i>Split Composite Names</i>
-----------	------------------------------

---

**Description**

Split a vector of composite names into a matrix of simple names.

**Usage**

```
strsplit2(x, split, ...)
```

**Arguments**

x	character vector
split	character to split each element of vector on, see <code>strsplit</code>
...	other arguments are passed to <code>strsplit</code>

**Details**

This function is the same as `strsplit` except that the output value is a matrix instead of a list. The first column of the matrix contains the first component from each element of `x`, the second column contains the second components etc. The number of columns is equal to the maximum number of components for any element of `x`.

The motivation for this function in the `limma` package is handle input columns which are composites of two or more annotation fields.

**Value**

A list containing components

Name	character vector of the same length as <code>x</code> contain first splits of each element
Annotation	character vector of the same length as <code>x</code> contain second splits of each element

**Author(s)**

Gordon Smyth

"3E7;W15277;No Annotation")
strsplit2(x,split=";")
```

subsetting

*Subset RGList, MAList, EListRaw, EList or MArrayLM Objects***Description**

Return an RGList, MAList, EListRaw, EList or MArrayLM object with only selected rows and columns of the original object.

**Usage**

```
## S3 method for class 'RGList'
object[i, j]
subsetListOfArrays(object, i, j, IJ, IX, I, JX)
```

**Arguments**

object	object of class RGList, MAList, EListRaw, EList or MArrayLM.
i, j	elements to extract. i subsets the probes or spots while j subsets the arrays.
IJ	character vector giving names of components that should be subsetted by i and j.
IX	character vector giving names of 2-dimensional components that should be subsetted by i only.
I	character vector giving names of vector components that should be subsetted by i.
JX	character vector giving names of 2-dimensional components whose row dimension corresponds to j.

**Details**

i, j may take any values acceptable for the matrix components of object. Either or both can be missing. See the [Extract](#) help entry for more details on subsetting matrices.

object[] will return the whole object unchanged. A single index object[i] will be taken to subset rows, so object[i] and object[i, ] are equivalent.

subsetListOfArrays is used internally as a utility function by the subsetting operations. It is not intended to be called directly by users. Values must be supplied for all arguments other than i and j.

**Value**

An object the same as object but containing data from the specified subset of rows and columns only.

**Author(s)**

Gordon Smyth

**Examples**

```
M <- A <- matrix(11:14,4,2)
rownames(M) <- rownames(A) <- c("a","b","c","d")
colnames(M) <- colnames(A) <- c("A","B")
MA <- new("MList",list(M=M,A=A))
MA[1:2,]
MA[c("a","b"),]
MA[1:2,2]
MA[,2]
```

---

summary

*Summaries of Microarray Data Objects*

---

**Description**

Briefly summarize microarray data objects.

**Usage**

```
## S3 method for class 'RGList'
summary(object, ...)
```

**Arguments**

object	an object of class RGList, MList, EListRaw, EList or MArrayLM
...	other arguments are not used

**Details**

The data objects are summarized as if they were lists, i.e., brief information about the length and type of the components is given.

**Value**

A table.

**Author(s)**

Gordon Smyth

[summary](#) in the base package.

[02.Classes](#) gives an overview of data classes used in LIMMA.

---

targetsA2C	<i>Convert Two-Color Targets Dataframe from One-Row-Per-Array to One-Row-Per-Channel</i>
------------	--

---

### Description

Convert a two-color targets dataframe with one row per array to one with one row per channel.

### Usage

```
targetsA2C(targets, channel.codes = c(1,2), channel.columns = list(Target=c("Cy3", "Cy5")),
           grep = FALSE)
```

### Arguments

targets	data.frame with one row per array giving information about target samples associated covariates.
channel.codes	numeric or character vector of length 2 giving codes for the channels
channel.columns	named list of character vectors of length 2. Each entry gives a pair of names of columns in targets which contain channel-specific information. This pair of columns should be assembled into one column in the output.
grep	logical, if TRUE then the channel column names are found by greping, i.e., the actual column names need only contain the names given by channel.columns as substrings

### Details

The targets dataframe holds information about the RNA samples used as targets in the microarray experiment. It is often read from a file using `readTargets`. This function is used to convert the dataframe from an array-orientated format with one row for each array and two columns for the two channels into a channel-orientated format with one row for each individual channel observations. In statistical terms, the first format treats the arrays as cases and treats the channels as repeated measurements. The second format treats the individual channel observations as cases. The second format may be more appropriate if the data is to be analyzed in terms of individual log-intensities.

### Value

data.frame with twice as many rows as targets. Any pair of columns named by channel.columns will now be one column.

### Author(s)

Gordon Smyth

### References

Smyth, GK, and Altman, NS (2013). Separate-channel analysis of two-channel microarrays: recovering inter-spot information. *BMC Bioinformatics* 14, 165. <http://www.biomedcentral.com/1471-2105/14/165>

targetsA2C(targets)
```

---

TestResults-class	<i>Matrix of Test Results - class</i>
-------------------	---------------------------------------

---

**Description**

A matrix-based class for storing the results of simultaneous tests. TestResults objects are normally created by [decideTests](#), [classifyTestsF](#), [classifyTestsT](#) or [classifyTestsP](#).

**Usage**

```
## S3 method for class 'TestResults'
summary(object, ...)
## S3 method for class 'TestResults'
labels(object, ...)
## S3 method for class 'TestResults'
levels(x)
```

**Arguments**

object, x	object of class TestResults
...	other arguments are not used

**Slots/List Components**

A TestResults object is essentially a numeric matrix with elements equal to 0, 1 or -1. Zero represents acceptance of the null hypothesis, 1 indicates rejection in favor of the right tail alternative and -1 indicates rejection in favor of the left tail alternative.

TestResults objects can be created by `new("TestResults", results)` where `results` is a matrix. Objects of this class contain no slots (other than `.Data`), although the attributes `dim` and `dimnames` may be treated as slots.

**Methods**

This class inherits directly from class `matrix` so any operation appropriate for matrices will work on objects of this class. [show](#) and `summary` methods are also implemented.

Functions in LIMMA which operate on TestResults objects include [heatDiagram](#), [vennCounts](#), [vennDiagram](#), [write.fit](#).

**Author(s)**

Gordon Smyth

**Examples**

```
## Not run:
# Assume a data object y and a design matrix
fit <- lmFit(y, design)
fit <- eBayes(fit)
results <- decideTests(fit)
summary(results)

## End(Not run)
```

tmixture

*Estimate Scale Factor in Mixture of t-Distributions***Description**

These functions estimate the unscaled standard deviation of the true (unobserved) log fold changes for differentially expressed genes. They are used by the functions `eBayes` and `eBayes` and are not intended to be called directly by users.

**Usage**

```
tmixture.vector(tstat, stdev.unscaled, df, proportion, v0.lim = NULL)
tmixture.matrix(tstat, stdev.unscaled, df, proportion, v0.lim = NULL)
```

**Arguments**

<code>tstat</code>	numeric vector or matrix of t-statistics. <code>tmixture.vector</code> assumes a vector while <code>tmixture.matrix</code> assumes a matrix.
<code>stdev.unscaled</code>	numeric vector or matrix, conformal with <code>tstat</code> , containing the unscaled standard deviations of the coefficients used to compute the t-statistics.
<code>df</code>	numeric vector giving the degrees of freedom associated with <code>tstat</code> .
<code>proportion</code>	assumed proportion of genes that are differentially expressed.
<code>v0.lim</code>	numeric vector of length 2 giving the lower and upper limits for the estimated unscaled standard deviations.

**Details**

The values in each column of `tstat` are assumed to follow a mixture of an ordinary t-distribution, with mixing proportion  $1 - \text{proportion}$ , and  $(v_0 + v_1)/v_1$  times a t-distribution, with mixing proportion `proportion`. Here  $v_1$  is `stdev.unscaled^2` and  $v_0$  is the value to be estimated.

**Value**

Numeric vector, of length equal to the number of columns of `tstat`, containing estimated  $v_0$  values.

**Author(s)**

Gordon Smyth

**See Also**[eBayes](#)

topGO

*Table of Top GO Terms or Top KEGG Pathways***Description**

Extract top GO terms from goana output or top KEGG pathways from kegga output.

**Usage**

```
topGO(results, ontology = c("BP", "CC", "MF"), sort = NULL, number = 20L,
      truncate.term = NULL)
topKEGG(results, sort = NULL, number = 20L, truncate.path = NULL)
```

**Arguments**

results	data frame produced by <a href="#">goana</a> or <a href="#">kegga</a> .
ontology	character vector of ontologies to be included in output. Elements should be one or more of "BP", "CC" or "MF".
sort	character vector of names of gene lists for which results are required. Should be one or more of the column names of results. Defaults to all gene lists.
number	maximum number of top GO terms or top KEGG pathways to list. For all terms or all pathways, set number=Inf.
truncate.term	truncate the name of the GO term at this number of characters.
truncate.path	truncate the name of the KEGG pathway at this number of characters.

**Details**

topGO organizes the output from [goana](#) into top-tables of the most significant GO terms. topKEGG similarly extracts the most significant KEGG pathways from [kegga](#) output. In either case, rows are sorted by the minimum p-value of any of the result columns specified by sort.

**Value**

Same as results but with rows subsetted by Ontology and sorted by p-value.

**Author(s)**

Gordon Smyth and Yifang Hu

```

---

topRomer

*Top Gene Set Testing Results from Romer*

---

**Description**

Extract a matrix of the top gene set testing results from the [romer](#) output.

**Usage**

```
topRomer(x, n=10, alternative="up")
```

**Arguments**

x	matrix which is the output from <a href="#">romer</a> .
n	number of top gene set testing results to be extracted.
alternative	character which can be one of the three possible alternative p values: "up", "down" or "mixed".

**Details**

This function takes the results from [romer](#) and returns a number of top gene set testing results that are sorted by the p values.

**Value**

matrix, which is sorted by the "up", "down" or "mixed" p values, with the rows corresponding to estimated p-values for the top number of gene sets and the columns corresponding to the number of genes for each gene set and the alternative hypotheses mixed, up, down.

**Author(s)**

Gordon Smyth and Yifang Hu

**See Also**

[romer](#)

**Examples**

```
# See romer for examples
```

topSplice

*Top table of differentially spliced genes or exons***Description**

Top table ranking the most differentially spliced genes or exons.

**Usage**

```
topSplice(fit, coef = ncol(fit), test = "simes", number = 10, FDR=1, sort.by = "p")
```

**Arguments**

fit	MArrayLM fit object produced by diffSplice.
coef	the coefficient (column) of fit for which differentially splicing is assessed.
test	character string specifying which statistical test to apply. Possible values are "simes", "F" or "t". "F" gives F-tests for each gene. "t" gives t-tests for each exon. "simes" gives genewise p-values derived from the t-tests after Simes adjustment for each gene.
number	integer, maximum number of rows to output.
FDR	numeric, only show exons or genes with false discovery rate less than this cutoff.
sort.by	character string specifying which column to sort results by. Possible values for "p", "logFC", "NExons" or "none". "logFC" is only available if test="t" and "NExons" is only available if test="simes" or test="F".

**Details**

Ranks genes or exons by evidence for differential splicing. The F-statistic tests for any differences in exon usage between experimental conditions. The exon-level t-statistics test for differences between each exon and all other exons for the same gene.

The Simes processes the exon-level p-values to give an overall call of differential splicing for each gene. It returns the minimum Simes-adjusted p-values for each gene.

The F-tests are likely to be powerful for genes in which several exons are differentially splices. The Simes p-values is likely to be more powerful when only a minority of the exons for a gene are differentially spliced. The exon-level t-tests are not recommended for formal error rate control.

**Value**

A data.frame with any annotation columns found in fit plus the following columns

logFC	log2-fold change of exon vs other exons for the same gene (if level="exon")
t	moderated t-statistic (if level="exon")
F	moderated F-statistic (if level="gene")
P.Value	p-value
FDR	false discovery rate

```

---

toptable	<i>Table of Top Genes from Linear Model Fit</i>
----------	---

---

**Description**

Extract a table of the top-ranked genes from a linear model fit.

**Usage**

```
topTable(fit, coef=NULL, number=10, genelist=fit$genes, adjust.method="BH",
         sort.by="B", resort.by=NULL, p.value=1, lfc=0, confint=FALSE)
toptable(fit, coef=1, number=10, genelist=NULL, A=NULL, eb=NULL, adjust.method="BH",
         sort.by="B", resort.by=NULL, p.value=1, lfc=0, confint=FALSE, ...)
topTableF(fit, number=10, genelist=fit$genes, adjust.method="BH",
         sort.by="F", p.value=1, lfc=0)
topTreat(fit, coef=1, sort.by="p", resort.by=NULL, ...)
```

**Arguments**

fit	list containing a linear model fit produced by <code>lmFit</code> , <code>lm.series</code> , <code>gls.series</code> or <code>mrlm</code> . For <code>topTable</code> , <code>fit</code> should be an object of class <code>MArrayLM</code> as produced by <code>lmFit</code> and <code>eBayes</code> .
coef	column number or column name specifying which coefficient or contrast of the linear model is of interest. For <code>topTable</code> , can also be a vector of column subscripts, in which case the gene ranking is by F-statistic for that set of contrasts.
number	maximum number of genes to list
genelist	data frame or character vector containing gene information. For <code>topTable</code> only, this defaults to <code>fit\$genes</code> .
A	matrix of A-values or vector of average A-values. For <code>topTable</code> only, this defaults to <code>fit\$Amean</code> .
eb	output list from <code>eBayes(fit)</code> . If <code>NULL</code> , this will be automatically generated.
adjust.method	method used to adjust the p-values for multiple testing. Options, in increasing conservatism, include "none", "BH", "BY" and "holm". See <a href="#">p.adjust</a> for the complete list of options. A <code>NULL</code> value will result in the default adjustment method, which is "BH".
sort.by	character string specifying statistic to rank genes by. Possible values for <code>topTable</code> and <code>toptable</code> are "logFC", "AveExpr", "t", "P", "p", "B" or "none". (Permitted synonyms are "M" for "logFC", "A" or "Amean" for "AveExpr", "T" for "t" and "p" for "P".) Possibilities for <code>topTableF</code> are "F" or "none". Possibilities for <code>topTreat</code> are as for <code>topTable</code> except for "B".

<code>resort.by</code>	character string specifying statistic to sort the selected genes by in the output data.frame. Possibilities are the same as for <code>sort.by</code> .
<code>p.value</code>	cutoff value for adjusted p-values. Only genes with lower p-values are listed.
<code>lfc</code>	minimum absolute log <sub>2</sub> -fold-change required. <code>topTable</code> and <code>topTableF</code> include only genes with (at least one) absolute log-fold-changes greater than <code>lfc</code> . <code>topTreat</code> does not remove genes but ranks genes by evidence that their log-fold-change exceeds <code>lfc</code> .
<code>confint</code>	logical, should confidence 95% intervals be output for logFC? Alternatively, can take a numeric value between zero and one specifying the confidence level required.
<code>...</code>	For <code>topTable</code> , other arguments are passed to <code>ebayes</code> (if <code>eb=NULL</code> ). For <code>topTreat</code> , other arguments are passed to <code>topTable</code> .

## Details

`topTable` is an earlier interface and is retained only for backward compatibility.

These functions summarize the linear model fit object produced by `lmFit`, `lm.series`, `gls.series` or `mr1m` by selecting the top-ranked genes for any given contrast. `topTable` and `topTableF` assume that the linear model fit has already been processed by `eBayes`. `topTreat` assumes that the fit has been processed by `treat`.

The p-values for the coefficient/contrast of interest are adjusted for multiple testing by a call to `p.adjust`. The "BH" method, which controls the expected false discovery rate (FDR) below the specified value, is the default adjustment method because it is the most likely to be appropriate for microarray studies. Note that the adjusted p-values from this method are bounds on the FDR rather than p-values in the usual sense. Because they relate to FDRs rather than rejection probabilities, they are sometimes called q-values. See `help("p.adjust")` for more information.

Note, if there is no good evidence for differential expression in the experiment, that it is quite possible for all the adjusted p-values to be large, even for all of them to be equal to one. It is quite possible for all the adjusted p-values to be equal to one if the smallest p-value is no smaller than  $1/n_{\text{genes}}$  where  $n_{\text{genes}}$  is the number of genes with non-missing p-values.

The `sort.by` argument specifies the criterion used to select the top genes. The choices are: "logFC" to sort by the (absolute) coefficient representing the log-fold-change; "A" to sort by average expression level (over all arrays) in descending order; "T" or "t" for absolute t-statistic; "P" or "p" for p-values; or "B" for the lods or B-statistic.

Normally the genes appear in order of selection in the output table. If a different order is wanted, then the `resort.by` argument may be useful. For example, `topTable(fit, sort.by="B", resort.by="logFC")` selects the top genes according to log-odds of differential expression and then orders the selected genes by log-ratio in decreasing order. Or `topTable(fit, sort.by="logFC", resort.by="logFC")` would select the genes by absolute log-fold-change and then sort them from most positive to most negative.

`topTableF` ranks genes on the basis of moderated F-statistics for one or more coefficients. If `topTable` is called and `coef` has two or more elements, then the specified columns will be extracted from `fit` and `topTableF` called on the result. `topTable` with `coef=NULL` is the same as `topTableF`, unless the fitted model `fit` has only one column.

`TopTable` output for all probes in original (unsorted) order can be obtained by `topTable(fit, sort="none", n=Inf)`. However `write.fit` or `write` may be preferable if the intention is to write the results to a file. A related method is `as.data.frame(fit)` which coerces an `MArrayLM` object to a data.frame.

By default number probes are listed. Alternatively, by specifying `p.value` and `number=Inf`, all genes with adjusted p-values below a specified value can be listed.

The argument `lfc` gives the ability to filter genes by log-fold change. This argument is not available for `topTreat` because `treat` already handles fold-change thresholding in a more sophisticated way.

### Value

A dataframe with a row for the number top genes and the following columns:

<code>genelist</code>	one or more columns of probe annotation, if <code>genelist</code> was included as input
<code>logFC</code>	estimate of the log <sub>2</sub> -fold-change corresponding to the effect or contrast (for <code>topTableF</code> there may be several columns of log-fold-changes)
<code>CI.L</code>	left limit of confidence interval for <code>logFC</code> (if <code>confint=TRUE</code> or <code>confint</code> is numeric)
<code>CI.R</code>	right limit of confidence interval for <code>logFC</code> (if <code>confint=TRUE</code> or <code>confint</code> is numeric)
<code>AveExpr</code>	average log <sub>2</sub> -expression for the probe over all arrays and channels, same as <code>Amean</code> in the <code>MarrayLM</code> object
<code>t</code>	moderated t-statistic (omitted for <code>topTableF</code> )
<code>F</code>	moderated F-statistic (omitted for <code>topTable</code> unless more than one coef is specified)
<code>P.Value</code>	raw p-value
<code>adj.P.Value</code>	adjusted p-value or q-value
<code>B</code>	log-odds that the gene is differentially expressed (omitted for <code>topTreat</code> )

If `fit` had unique rownames, then the `row.names` of the above data.frame are the same in sorted order. Otherwise, the `row.names` of the data.frame indicate the row number in `fit`. If `fit` had duplicated row names, then these are preserved in the `ID` column of the data.frame, or in `ID0` if `genelist` already contained an `ID` column.

### Note

Although `topTable` enables users to set p-value and `lfc` cutoffs simultaneously, this is not generally recommended. If the fold changes and p-values are not highly correlated, then the use of a fold change cutoff can increase the false discovery rate above the nominal level. Users wanting to use fold change thresholding are usually recommended to use `treat` and `topTreat` instead.

In general, the adjusted p-values returned by `adjust.method="BH"` remain valid as FDR bounds only when the genes remain sorted by p-value. Resorting the table by log-fold-change can increase the false discovery rate above the nominal level for genes at the top of resorted table.

---

tricubeMovingAverage *Moving Average Smoother With Tricube Weights*

---

### Description

Apply a moving average smoother with tricube distance weights to a numeric vector.

### Usage

```
tricubeMovingAverage(x, span=0.5, power=3)
```

### Arguments

x	numeric vector
span	the smoother span. This gives the proportion of x values that contribute to each moving average. Larger values give more smoothness. Should be positive but not greater than 1.
power	a positive exponent used to compute the tricube weights. power=3 gives the usual tricube weights. Smaller values give more even weighting. Should be greater than 0.

### Details

This function smooths a vector (considered as a time series) using a moving average with tricube weights. Specifically, the function computes running weighted means of  $w$  consecutive values of  $x$ , where the window width  $w$  is equal to  $2*h+1$  with  $h = 2*\text{floor}(\text{span}*\text{length}(x)/2)$ . The window width  $w$  is always odd so that each window has one of the original  $x$  values at its center. Each weighted mean uses a set of tricube weights so that values near the ends of the window receive less weight.

The smoother returns a vector of the same length as input. At the start and end of the vector, the series is considered to be extended by missing values, and the weighted average is computed only over the observed values. In other words, the window width is reduced to  $h+1$  at the boundaries with asymmetric weights.

The result of this function is similar to a least squares loess curve of degree zero, with a couple of differences. First, a continuity correction is applied when computing the distance to neighbouring points, so that exactly  $w$  points are included with positive weights in each average. Second, the span halves at the end points so that the smoother is more sensitive to trends at the ends.

The `filter` function in the `stats` package is called to do the low-level calculations.

This function is used by [barcodeplot](#) to compute enrichment worms.

### Value

Numeric vector of same length as  $x$  containing smoothed values.

### Author(s)

Gordon Smyth

trigammaInverse	<i>Inverse Trigamma Function</i>
-----------------	----------------------------------

---

**Description**

The inverse of the trigamma function.

**Usage**

```
trigammaInverse(x)
```

**Arguments**

x                    numeric vector or array

**Details**

The function uses Newton's method with a clever starting value to ensure monotonic convergence.

**Value**

Numeric vector or array y satisfying  $\text{trigamma}(y) = x$ .

**Note**

This function does not accept a data.frame as argument although the base package function `trigamma` does.

**Author(s)**

Gordon Smyth

**See Also**

This function is the inverse of [trigamma](#) in the base package.

This function is called by [fitFDist](#).

**Examples**

```
y <- trigammaInverse(5)
trigamma(y)
```

---

trimWhiteSpace	<i>Trim Leading and Trailing White Space</i>
----------------	--

---

**Description**

Trims leading and trailing white space from character strings.

**Usage**

```
trimWhiteSpace(x)
```

**Arguments**

x                      character vector

**Value**

A character vector of the same length as x in which leading and trailing white space has been stripped off each value.

**Author(s)**

Tim Beissbarth and Gordon Smyth

**See Also**

An overview of LIMMA functions for reading data is given in [03.ReadingData](#).

**Examples**

```
x <- c("a ", " b ")
trimWhiteSpace(x)
```

---

uniquegenelist	<i>Eliminate Duplicate Names from the Gene List</i>
----------------	---

---

**Description**

Eliminate duplicate names from the gene list. The new list is shorter than the full list by a factor of ndups.

**Usage**

```
uniquegenelist(genelist, ndups=2, spacing=1)
```

**Arguments**

genelist                vector of gene names  
ndups                    number of duplicate spots. The number of rows of genelist must be divisible by ndups.  
spacing                  the spacing between duplicate names in genelist

**Value**

A vector of length `length(geneList)/ndups` containing each gene name once only.

**Author(s)**

Gordon Smyth

**See Also**

[unwrapdups](#)

**Examples**

```
geneList <- c("A", "A", "B", "B", "C", "C", "D", "D")
uniquegeneList(geneList, ndups=2)
geneList <- c("A", "B", "A", "B", "C", "D", "C", "D")
uniquegeneList(geneList, ndups=2, spacing=2)
```

---

unwrapdups

*Unwrap Duplicate Spot Values from Rows into Columns*

---

**Description**

Reshape a matrix so that a set of consecutive rows becomes a single row in the output.

**Usage**

```
unwrapdups(M, ndups=2, spacing=1)
```

**Arguments**

<code>M</code>	a matrix.
<code>ndups</code>	number of duplicate spots. The number of rows of <code>M</code> must be divisible by <code>ndups</code> .
<code>spacing</code>	the spacing between the rows of <code>M</code> corresponding to duplicate spots, <code>spacing=1</code> for consecutive spots

**Details**

This function is used on matrices corresponding to a series of microarray experiments. Rows corresponding to duplicate spots are re-arranged to that all values corresponding to a single gene are on the same row. This facilitates fitting models or computing statistics for each gene.

**Value**

A matrix containing the same values as `M` but with fewer rows and more columns by a factor of `ndups`. Each set of `ndups` rows in `M` is strung out to a single row so that duplicate values originally in consecutive rows in the same column are in consecutive columns in the output.

**Author(s)**

Gordon Smyth

**Examples**

```
M <- matrix(1:12,6,2)
unwrapdups(M, ndups=2)
unwrapdups(M, ndups=3)
unwrapdups(M, ndups=2, spacing=3)
```

venn

*Venn Diagrams***Description**

Compute classification counts and draw a Venn diagram.

**Usage**

```
vennCounts(x, include="both")
vennDiagram(object, include="both", names=NULL, mar=rep(1,4), cex=c(1.5,1,0.7), lwd=1,
            circle.col=NULL, counts.col=NULL, show.include=NULL, ...)
```

**Arguments**

x	a TestResults matrix. This is numeric matrix of 0's, 1's and -1's indicating significance of a test or membership of a set. Each row corresponds to a gene and each column to a contrast or set. Usually created by <a href="#">decideTests</a> .
object	either a TestResults matrix or a VennCounts object produced by vennCounts.
include	character vector specifying whether all differentially expressed genes should be counted, or whether the counts should be restricted to genes changing in a certain direction. Choices are "both" for all differentially expressed genes, "up" for up-regulated genes only or "down" for down-regulated genes only. If include=c("up", "down") then both the up and down counts will be shown. This argument is ignored if object if object is already a vennCounts object.
names	character vector giving names for the sets or contrasts
mar	numeric vector of length 4 specifying the width of the margins around the plot. This argument is passed to par.
cex	numerical vector of length 3 giving scaling factors for large, medium and small text on the plot.
lwd	numerical value giving the amount by which the circles should be scaled on the plot. See par.
circle.col	vector of colors for the circles. See par for possible values.
counts.col	vector of colors for the counts. Of same length as include. See par for possible values.
show.include	logical value whether the value of include should be printed on the plot. Defaults to FALSE if include is a single value and TRUE otherwise
...	any other arguments are passed to plot

**Details**

Each column of  $x$  corresponds to a contrast or set, and the entries of  $x$  indicate membership of each row in each set or alternatively the significance of each row for each contrast. In the latter case, the entries can be negative as well as positive to indicate the direction of change.

`vennCounts` can collate intersection counts for any number of sets. `vennDiagram` can plot up to five sets.

**Value**

`vennCounts` produces an object of class "VennCounts". This contains only one slot, which is numerical matrix with  $2^{\text{ncol}\{x\}}$  rows and  $\text{ncol}\{x\}+1$  columns. Each row corresponds to a particular combination of set memberships. The first  $\text{ncol}\{x\}$  columns of output contain 1 or 0 indicating membership or not in each set. The last column called "Counts" gives the number of rows of  $x$  corresponding to that combination of memberships.

`vennDiagram` produces no output but causes a plot to be produced on the current graphical device.

**Author(s)**

Gordon Smyth, James Wettenhall, Francois Pepin, Steffen Moeller and Yifang Hu

**See Also**

An overview of linear model functions in limma is given by [06.LinearModels](#).

**Examples**

```
Y <- matrix(rnorm(100*6),100,6)
Y[1:10,3:4] <- Y[1:10,3:4]+3
Y[1:20,5:6] <- Y[1:20,5:6]+3
design <- cbind(1,c(0,0,1,1,0,0),c(0,0,0,0,1,1))
fit <- eBayes(lmFit(Y,design))
results <- decideTests(fit)
a <- vennCounts(results)
print(a)
mfrow.old <- par()$mfrow
par(mfrow=c(1,2))
vennDiagram(a)
vennDiagram(results,
  include=c("up", "down"),
  counts.col=c("red", "blue"),
  circle.col = c("red", "blue", "green3"))
par(mfrow=mfrow.old)
```

---

volcanoplot

*Volcano Plot*

---

**Description**

Creates a volcano plot for a specified coefficient of a linear model.

**Usage**

```
volcanoplot(fit, coef = 1, style = "p-value", highlight = 0, names = fit$genes$ID, hl.col="blue",
            xlab = "Log2 Fold Change", ylab = NULL, pch=16, cex=0.35, ...)
```

**Arguments**

fit	an MArrayLM fitted linear model object.
coef	index indicating which coefficient of the linear model is to be plotted.
style	character string indicating which significance statistic to plot on the y-axis. Possibilities are "p-value" or "B-statistic".
highlight	number of top genes to be highlighted by name.
names	character vector of length nrow(fit) giving gene names. Only used if highlight > 0.
hl.col	color for the gene names. Only used if highlight > 0.
xlab	character string giving label for x-axis
ylab	character string giving label for y-axis
pch	vector or list of plotting characters.
cex	numeric vector of plot symbol expansions.
...	any other arguments are passed to plot

**Details**

A volcano plot displays log fold changes on the x-axis versus a measure of statistical significance on the y-axis. Here the significance measure can be  $-\log(\text{p-value})$  or the B-statistics, which give the posterior log-odds of differential expression.

The plot is optionally annotated with the names of the most significant genes.

**Value**

No value is returned but a plot is created on the current graphics device.

voom

*Transform RNA-Seq Data Ready for Linear Modelling***Description**

Transform count data to log<sub>2</sub>-counts per million (logCPM), estimate the mean-variance relationship and use this to compute appropriate observation-level weights. The data are then ready for linear modelling.

**Usage**

```
voom(counts, design = NULL, lib.size = NULL, normalize.method = "none",
      span = 0.5, plot = FALSE, save.plot = FALSE, ...)
```

**Arguments**

counts	a numeric matrix containing raw counts, or an ExpressionSet containing raw counts, or a DGEList object. Counts must be non-negative and NAs are not permitted.
design	design matrix with rows corresponding to samples and columns to coefficients to be estimated. Defaults to the unit vector meaning that samples are treated as replicates.
lib.size	numeric vector containing total library sizes for each sample. Defaults to the normalized (effective) library sizes in counts if counts is a DGEList or to the columnwise count totals if counts is a matrix.
normalize.method	the microarray-style normalization method to be applied to the logCPM values (if any). Choices are as for the method argument of normalizeBetweenArrays when the data is single-channel. Any normalization factors found in counts will still be used even if normalize.method="none".
span	width of the lowess smoothing window as a proportion.
plot	logical, should a plot of the mean-variance trend be displayed?
save.plot	logical, should the coordinates and line of the plot be saved in the output?
...	other arguments are passed to lmFit.

**Details**

This function is intended to process RNA-Seq or ChIP-Seq data prior to linear modelling in limma. voom is an acronym for mean-variance modelling at the observational level. The idea is to estimate the mean-variance relationship in the data, then use this to compute an appropriate precision weight for each observation. Count data always show marked mean-variance relationships. Raw counts show increasing variance with increasing count size, while log-counts typically show a decreasing mean-variance trend. This function estimates the mean-variance trend for log-counts, then assigns a weight to each observation based on its predicted variance. The weights are then used in the linear modelling process to adjust for heteroscedasticity.

voom performs the following specific calculations. First, the counts are converted to logCPM values, adding 0.5 to all the counts to avoid taking the logarithm of zero. The matrix of logCPM values is then optionally normalized. The lmFit function is used to fit row-wise linear models. The lowess function is then used to fit a trend to the square-root-standard-deviations as a function of average

logCPM. The trend line is then used to predict the variance of each logCPM value as a function of its fitted value, and the inverse variances become the estimated precision weights.

For good results, the counts matrix should be filtered to remove rows with very low counts before running `voom()`. The `filterByExpr` function in the `edgeR` package can be used for that purpose.

If `counts` is a `DGEList` object from the `edgeR` package, then `voom` will use the normalization factors found in the object when computing the logCPM values. In other words, the logCPM values are computed from the effective library sizes rather than the raw library sizes. If the `DGEList` object has been scale-normalized in `edgeR`, then it is usual to leave `normalize.method="none"` in `voom`, i.e., the logCPM values should not usually be re-normalized in the `voom` call.

The `voom` method is similar in purpose to the `limma-trend` method, which uses `eBayes` or `treat` with `trend=TRUE`. The `voom` method incorporates the mean-variance trend into the precision weights, whereas `limma-trend` incorporates the trend into the empirical Bayes moderation. The `voom` method takes into account the sequencing depths (library sizes) of the individual columns of counts and applies the mean-variance trend on an individual observation basis. `limma-trend`, on the other hand, assumes that the library sizes are not wildly different and applies the mean-variance trend on a gene-wise basis. As noted by Law et al (2014), `voom` should be more powerful than `limma-trend` if the library sizes are very different but, otherwise, the two methods should give similar results.

## Value

An `EList` object with the following components:

<code>E</code>	numeric matrix of normalized expression values on the log2 scale
<code>weights</code>	numeric matrix of inverse variance weights
<code>design</code>	design matrix
<code>lib.size</code>	numeric vector of total normalized library sizes
<code>genes</code>	dataframe of gene annotation extracted from counts
<code>voom.xy</code>	if <code>save.plot</code> , list containing x and y coordinates for points in mean-variance plot
<code>voom.line</code>	if <code>save.plot</code> , list containing coordinates of loess line in the mean-variance plot

vooma

*Convert Mean-Variance Trend to Observation-specific Precision Weights for Microarray Data*

**Description**

Estimate the mean-variance relationship and use this to compute appropriate observational-level weights.

**Usage**

```
vooma(y, design=NULL, correlation, block=NULL, plot=FALSE, span=NULL)
voomaByGroup(y, group, design=NULL, correlation, block=NULL,
             plot=FALSE, span=NULL, col=NULL, lwd=1, alpha=0.5,
             pch=16, cex=0.3, legend="topright")
```

**Arguments**

y	a numeric matrix, EList object, or any object containing log-expression data that can be coerced to a matrix.
design	design matrix with rows corresponding to samples and columns to coefficients to be estimated. Defaults to the unit vector meaning that samples are treated as replicates.
block	vector or factor specifying a blocking variable on the arrays. Has length equal to the number of arrays.
correlation	intra-block correlation
span	width of the smoothing window, as a proportion of the data set.
plot	logical value indicating whether a plot of mean-variance trend should be displayed.
group	categorical vector or factor giving group membership of columns of y.
col	vector of colors for plotting group trends
lwd	line width for plotting group trends
pch	plotting character. Default is integer code 16 which gives a solid circle. If a vector, then should be of length nrow(y).

cex	numeric vector of plot symbol expansions. If a vector, then should be of length equal to number of groups.
alpha	transparency of points, on scale from 0 for fully transparent to 1 for fully opaque.
legend	character string giving position to place legend.

### Details

vooma is an acronym for mean-variance modelling at the observational level for arrays.

vooma estimates the mean-variance relationship in the data, and uses this to compute appropriate weights for each observation. This done by estimating a mean-variance trend, then interpolating this trend to obtain a precision weight (inverse variance) for each observation. The weights can then used by other functions such as `lmFit` to adjust for heteroscedasticity.

voomaByGroup estimates precision weights separately for each group. In other words, it allows for different mean-variance curves in different groups.

### Value

An EList object with the following components:

E	numeric matrix of as input
weights	numeric matrix of weights
design	numeric matrix of experimental design
genes	dataframe of gene annotation, only if counts was a DGEList object

### Author(s)

Charity Law and Gordon Smyth

voomWithQualityWeights

*Combining observational-level with sample-specific quality weights for RNA-seq analysis*

---

### Description

Combine voom observational-level weights with sample-specific quality weights in a designed experiment.

**Usage**

```
voomWithQualityWeights(counts, design=NULL, lib.size=NULL, normalize.method="none",
  plot=FALSE, span=0.5, var.design=NULL, method="genebygene", maxiter=50,
  tol=1e-10, trace=FALSE, col=NULL, ...)
```

**Arguments**

counts	a numeric matrix containing raw counts, or an ExpressionSet containing raw counts, or a DGEList object.
design	design matrix with rows corresponding to samples and columns to coefficients to be estimated. Defaults to the unit vector meaning that samples are treated as replicates.
lib.size	numeric vector containing total library sizes for each sample. If NULL and counts is a DGEList then, the normalized library sizes are taken from counts. Otherwise library sizes are calculated from the columnwise counts totals.
normalize.method	normalization method to be applied to the logCPM values. Choices are as for the method argument of normalizeBetweenArrays when the data is single-channel.
plot	logical, should a plot of the mean-variance trend and sample-specific weights be displayed?
span	width of the lowess smoothing window as a proportion.
var.design	design matrix for the variance model. Defaults to the sample-specific model (i.e. each sample has a distinct variance) when NULL.
method	character string specifying the estimating algorithm to be used. Choices are "genebygene" and "reml".
maxiter	maximum number of iterations allowed.
tol	convergence tolerance.
trace	logical variable. If true then output diagnostic information at each iteration of the "reml" algorithm, or at every 1000th iteration of the "genebygene" algorithm.
col	colours to use in the barplot of sample-specific weights (only used if plot=TRUE). If NULL, bars are plotted in grey.
...	other arguments are passed to lmFit.

**Details**

This function is intended to process RNA-Seq data prior to linear modelling in limma.

It combines observational-level weights from voom with sample-specific weights estimated using the arrayWeights function.

**Value**

An [EList](#) object similar to that from voom, with an extra column `sample.weights` containing the vector of sample quality factors added to the `targets` data.frame. The weights component combines the sample weights and the usual voom precision weights.

**Author(s)**

weighted.median	<i>Weighted Median</i>
-----------------	------------------------

---

## Description

Compute a weighted median of a numeric vector.

## Usage

```
weighted.median(x, w, na.rm = FALSE)
```

## Arguments

- |       |   |
|-------|---|
| x     | a numeric vector containing the values whose mean is to be computed.                                  |
| w     | a vector of weights the same length as x giving the weights to use for each element of x.             |
| na.rm | a logical value indicating whether NA values in x should be stripped before the computation proceeds. |

## Details

If w is missing then all elements of x are given the same weight.

Missing values in w are not handled.

The weighted median is the median of the discrete distribution with values given by x and probabilities given by w/sum(w).

## Value

numeric value giving the weighted median

## See Also

[median](#), [weighted.mean](#)

**Examples**

```
## GPA from Siegel 1994
wt <- c(5, 5, 4, 1)/15
x <- c(3.7, 3.3, 3.5, 2.8)
xm <- weighted.median(x, wt)
```

---

 weightedLoess

*Lowess fit with weighting*

---

**Description**

Fit robust lowess curves of degree 1 to weighted covariates and responses.

**Usage**

```
weightedLowess(x, y, weights = rep(1, length(y)),
               delta=NULL, npts = 200, span = 0.3, iterations = 4)
```

**Arguments**

x	a numeric vector of covariates
y	a numeric vector of response values
weights	a numeric vector containing frequency weights for each covariate
delta	a numeric scalar specifying the maximum distance between adjacent points
npts	an integer scalar specifying the approximate number of points to use when computing delta
span	a numeric scalar specifying the width of the smoothing window as a proportion of the total weight
iterations	an integer scalar specifying the number of robustifying iterations

**Details**

This function extends the lowess algorithm to handle non-negative prior weights. These weights are used during span calculations such that the span distance for each point must include the specified proportion of all weights. They are also applied during weighted linear regression to compute the fitted value (in addition to the tricube weights determined by span). For integer weights, the prior weights are equivalent to using `rep(..., w)` on `x` and `y` prior to fitting.

For large vectors, running time is reduced by only performing locally weighted regression for several points. Fitted values for all points adjacent to the chosen points are computed by linear interpolation between the chosen points. For this purpose, the first and last points are always chosen. Note that the regression itself uses all (neighbouring) points.

Points are defined as adjacent to a chosen point if the distance to the latter is positive and less than `delta`. The first chosen point is that corresponding to the smallest covariate; the next chosen point is then the next non-adjacent point, and so on. By default, the smallest `delta` is chosen to obtain a number of chosen points approximately equal to the specified `npts`. Increasing `npts` or supplying a small `delta` will improve the accuracy of the fit (i.e. closer to the full lowess procedure) at the cost of running time.

Robustification is performed using the magnitude of the residuals. Residuals greater than 6 times the median residual are assigned weights of zero. Otherwise, Tukey's biweight function is applied. Weights are then used for weighted linear regression. Greater values of `iterations` will provide greater robustness.

**Value**

A list of numeric vectors for the fitted responses, the residuals, the robustifying weights and the chosen delta.

y <- rt(100,df=4)
x <- runif(100)
w <- runif(100)
out <- weightedLowess(x, y, w, span=0.7)
plot(x,y,cex=w)
o <- order(x)
lines(x[o],out$fitted[o],col="red")
```

---

write.fit

*Write MArrayLM Object to a File*

---

**Description**

Write a microarray linear model fit to a file.

**Usage**

```
write.fit(fit, results = NULL, file, digits = NULL,
          adjust = "none", method = "separate", F.adjust = "none",
          quote = FALSE, sep = "\t", row.names = TRUE, ...)
```

**Arguments**

fit	object of class MArrayLM containing the results of a linear model fit
results	object of class TestResults
file	character string giving name of file
digits	integer indicating rounding precision for output values. If NULL, then no rounding is done.
adjust	character string specifying multiple-testing adjustment method for the t-statistic P-values, e.g., "BH". See <a href="#">p.adjust</a> for the available options. If NULL or "none" then the P-values are not adjusted.

method	character string, should the P-value adjustment be "global" or "separate" for each contrast.
F.adjust	character string specifying adjustment method for the F-statistic P-values.
quote	logical. If TRUE, any character or factor columns will be surrounded by double quotes.
sep	the field separator string. Values in the output file will be separated by this string.
row.names	logical, whether to include row names in output file.
...	other arguments are passed to <code>write.table</code>

### Details

This function writes a tab-delimited text file containing for each gene (1) the average log<sub>2</sub>-intensity, (2) the coefficients or contrasts (log<sub>2</sub>-fold-changes), (3) moderated t-statistics, (4) t-statistic P-values, (5) F-statistic if available, (6) F-statistic P-values if available, (7) classification if available and (8) gene names and annotation.

### Value

No value is produced but a file is written to the current working directory.

### Author(s)

Gordon Smyth

---

wsva

*Weighted Surrogate Variable Analysis*

---

### Description

Calculate surrogate variables from the singular vectors of the linear model residual space.

### Usage

```
wsva(y, design, n.sv = 1L, weight.by.sd = FALSE, plot = FALSE, ...)
```

### Arguments

y	numeric matrix giving log-expression or log-ratio values for a series of microarrays, or any object that can be coerced to a matrix including ExpressionSet, MAList, EList or PLMSet objects. Rows correspond to genes and columns to samples.
design	design matrix
n.sv	number of surrogate variables required.
weight.by.sd	logical, should the surrogate variables be especially tuned to the more variable genes?

plot            logical. If TRUE, plots the proportion of variance explained by each surrogate variable.

...            other arguments can be included that would be suitable for `lmFit`.

### Details

The function constructs surrogate variables that explain a high proportion of the residual variability for many of the genes. The surrogate variables can be included in the design matrix to remove unwanted variation. The surrogate variables are constructed from the singular vectors of a representation of the linear model residual space.

If `weight.by.sd=FALSE`, then the method is a simplification of the approach by Leek and Storey (2007).

### Value

Numeric matrix with `ncol(y)` rows and `n.sv` columns containing the surrogate variables.

### Author(s)

Gordon Smyth and Yifang Hu

### References

Leek, JT, Storey, JD (2007). Capturing heterogeneity in gene expression studies by surrogate variable analysis. *PLoS Genetics* 3, 1724-1735.

---

zscore	<i>Z-score Equivalents</i>
--------	----------------------------

---

### Description

Compute z-score equivalents of non-normal random deviates.

### Usage

```
zscore(q, distribution, ...)
zscoreGamma(q, shape, rate = 1, scale = 1/rate)
zscoreT(x, df, approx=FALSE)
tZscore(x, df)
zscoreHyper(q, m, n, k)
```

### Arguments

q, x            numeric vector or matrix giving deviates of a random variable

distribution    character name of probability distribution for which a cumulative distribution function exists

...            other arguments specify distributional parameters and are passed to the cumulative distribution function

shape          gamma shape parameter (>0)

rate           gamma rate parameter (>0)

scale	gamma scale parameter (>0)
df	degrees of freedom (>0 for zscoreT or >=1 for tZscore)
approx	logical, if TRUE then a fast approximation is used to convert t-statistics into z-scores. If FALSE, z-scores will be exact.
m	as for <a href="#">qhyper</a>
n	as for <a href="#">qhyper</a>
k	as for <a href="#">qhyper</a>

### Details

These functions compute the standard normal deviates which have the same quantiles as the given values in the specified distribution. For example, if `z <- zscoreT(x, df=df)` then `pnorm(z)` equals `pt(x, df=df)`.

`zscore` works for any distribution for which a cumulative distribution function (like `pnorm`) exists in R. The argument `distribution` is the name of the cumulative distribution function with the "p" removed.

`zscoreGamma`, `zscoreT` and `zscoreHyper` are specific functions for the gamma, t and hypergeometric distributions respectively.

`tZscore` is the inverse of `zscoreT`, and computes t-distribution equivalents for standard normal deviates.

The transformation to z-scores is done by converting to log tail probabilities, and then using `qnorm`. For numerical accuracy, the left or right tail is used, depending on which is likely to be smaller.

If `approx=TRUE`, then the approximation from Hill (1970) is used to convert t-statistics to z-scores directly without computing tail probabilities. Brophy (1987) showed this to be most accurate of a variety of possible closed-form transformations.

### Value

Numeric vector giving equivalent deviates from the standard normal distribution. The exception is `tZscore` which gives deviates from the specified t-distribution.

### Author(s)

Gordon Smyth

**Examples**

```
# First three are equivalent
zscore(c(1,2.5), dist="gamma", shape=0.5, scale=2)
zscore(c(1,2.5), dist="chisq", df=1)
zscoreGamma(c(1,2.5), shape=0.5, scale=2)

zscoreT(2, df=3)
tZscore(2, df=3)
```
