Package ‘S4Vectors’

January 8, 2024

Title Foundation of vector-like and list-like containers in Bioconductor

Description The S4Vectors package defines the Vector and List virtual classes and a set of generic functions that extend the semantic of ordinary vectors and lists in R. Package developers can easily implement vector-like or list-like objects as concrete subclasses of Vector or List. In addition, a few low-level concrete subclasses of general interest (e.g. DataFrame, Rle, Factor, and Hits) are implemented in the S4Vectors package itself (many more are implemented in the IRanges package and in other Bioconductor infrastructure packages).

aggregate-methods

The *S4Vectors* package defines *aggregate* methods for *Vector*, *Rle*, and *List* objects.

**Usage**

```r
## S4 method for signature 'Vector'
aggregate(x, by, FUN, start=NULL, end=NULL, width=NULL,
          frequency=NULL, delta=NULL, ..., simplify=TRUE)

## S4 method for signature 'Rle'
aggregate(x, by, FUN, start=NULL, end=NULL, width=NULL,
          frequency=NULL, delta=NULL, ..., simplify=TRUE)

## S4 method for signature 'List'
aggregate(x, by, FUN, start=NULL, end=NULL, width=NULL,
          frequency=NULL, delta=NULL, ..., simplify=TRUE)
```

**Arguments**

- **x** A *Vector*, *Rle*, or *List* object.
- **by** An object with *start*, *end*, and *width* methods.
  - If *x* is a *List* object, the *by* parameter can be a *IntegerRangesList* object to aggregate within the list elements rather than across them. When *by* is a *IntegerRangesList* object, the output is either a *SimpleAtomicList* object, if possible, or a *SimpleList* object, if not.
- **FUN** The function, found via `match.fun`, to be applied to each subset of *x*.

**Description**

*aggregate* methods Compute summary statistics of subsets of vector-like objects.
aggregate-methods

start, end, width
   The start, end, and width of the subsets. If by is missing, then two of the three
   must be supplied and have the same length.

frequency, delta
   Optional arguments that specify the sampling frequency and increment within
   the subsets (in the same fashion as window from the stats package does).

...  
   Optional arguments to FUN.

simplify 
   A logical value specifying whether the result should be simplified to a vector or
   matrix if possible.

Details

Subsets of x can be specified either via the by argument or via the start, end, width, frequency,
and delta arguments.

For example, if start and end are specified, then:

    aggregate(x, FUN=FUN, start=start, end=end, ..., simplify=simplify)

is equivalent to:

    sapply(seq_along(start),
           function(i) FUN(x[start[i]:end[i]], ...), simplify=simplify)

(replace x[start[i]:end[i]] with 2D-style subsetting x[start[i]:end[i], ] if x is a DataFrame
object).

See Also

• The aggregate function in the stats package.

• Vector, Rle, List, and DataFrame objects.

• The start, end, and width generic functions defined in the BiocGenerics package.

Examples

x <- Rle(10:2, 1:9)
aggregate(x, x > 4, mean)
aggregate(x, FUN=mean, start=1:26, width=20)

## Note that aggregate() works on a DataFrame object the same way it
## works on an ordinary data frame:
aggregate(DataFrame(state.x77), list(Region=state.region), mean)
aggregate(weight ~ feed, data=DataFrame(chickwts), mean)

library(IRanges)
by <- IRanges(start=1:26, width=20, names=LETTERS)
aggregate(x, by, is.unsorted)
Annotated-class

Description

The virtual class `Annotated` is used to standardize the storage of metadata with a subclass.

Details

The `Annotated` class supports the storage of global metadata in a subclass. This is done through the `metadata` slot that stores a list object.

Accessors

In the code snippet below, `x` is an `Annotated` object.

```r
metadata(x), metadata(x) <- value: Get or set the list holding arbitrary R objects as annotations. May be, and often is, empty.
```

Author(s)

P. Aboyoun

See Also

The `Vector` class, which extends `Annotated` directly.

Examples

```r
showClass("Annotated") # shows (some of) the known subclasses

## If the IRanges package was not already loaded, this will show
## more subclasses:
library(IRanges)
showClass("Annotated")
```

bindROWS

Combine objects along their ROWS or COLS

Description

`bindROWS` and `bindCOLS` are low-level generic functions defined in the `S4Vectors` package for binding objects along their 1st or 2nd dimension. They are the workhorses behind higher-level operations like `c()`, `rbind()`, or `cbind()` on most vector-like or rectangular objects defined in Bioconductor.

They are not intended to be used directly by the end user.
Usage

bindROWS(x, objects=list(), use.names=TRUE, ignore.mcols=FALSE, check=TRUE)
bindCOLS(x, objects=list(), use.names=TRUE, ignore.mcols=FALSE, check=TRUE)

Arguments

- **x**: An S4 object.
- **objects**: A list of S4 objects to bind to x. They should typically (but not necessarily) have the same class as x.
- **use.names**: Should the names on the input objects be propagated? By default they are.
- **ignore.mcols**: Should the metadata columns on the input objects be ignored? By default they are not (i.e. they are propagated).
- **check**: Should the result object be validated before being returned to the user? By default it is.

Value

An object of the same class as x.

Author(s)

Hervé Pagès

- The `NROW` and `NCOL` generic functions defined in the `BiocGenerics` package.

---

**character-utils**

---

Some utility functions to operate on strings

Description

Some low-level string utilities to operate on ordinary character vectors. For more advanced string manipulations, see the `Biostrings` package.

Usage

unstrsplit(x, sep="")

## more to come...

Arguments

- **x**: A list-like object where each list element is a character vector, or a character vector (identity).
- **sep**: A single string containing the separator.
Details

`unstrsplit(x, sep)` is equivalent to (but much faster than) `sapply(x, paste0, collapse=sep).` It performs the reverse transformation of `strsplit( , fixed=TRUE),` that is, if `x` is a character vector with no NAs and `sep` a single string, then `unstrsplit(strsplit(x, split=sep, fixed=TRUE), sep)` is identical to `x`. A notable exception to this though is when `strsplit` finds a match at the end of a string, in which case the last element of the output (which should normally be an empty string) is not returned (see `?strsplit` for the details).

Value

A character vector with one string per list element in `x`.

Author(s)

Hervé Pagès

See Also

- The `strsplit` function in the `base` package.

Examples

```r
x <- list(A=c("abc", "XY"), B=NULL, C=letters[1:4])
unstrsplit(x)
unstrsplit(x, sep=" ,")
unstrsplit(x, sep=" => ")

data(islands)
x <- names(islands)
y <- strsplit(x, split=" ", fixed=TRUE)
x2 <- unstrsplit(y, sep=" ")
stopifnot(identical(x, x2))

## But...
names(x) <- x
y <- strsplit(x, split="in", fixed=TRUE)
x2 <- unstrsplit(y, sep="in")
y[x != x2]
## In other words: strsplit() behavior sucks :-/
```

DataFrame-class

Description

The `DataFrame` class extends the `RectangularData` virtual class supports the storage of any type of object (with `length` and `[` methods) as columns.
Details

On the whole, the DataFrame behaves very similarly to data.frame, in terms of construction, subsetting, splitting, combining, etc. The most notable exceptions have to do with handling of the row names:

1. The row names are optional. This means calling rownames(x) will return NULL if there are no row names. Of course, it could return seq_len(nrow(x)), but returning NULL informs, for example, combination functions that no row names are desired (they are often a luxury when dealing with large data).
2. The row names are not required to be unique.
3. Subsetting by row names does not use partial matching.

As DataFrame derives from Vector, it is possible to set an annotation string. Also, another DataFrame can hold metadata on the columns.

For a class to be supported as a column, it must have length and [ methods, where [ supports subsetting only by i and respects drop=FALSE. Optionally, a method may be defined for the showAsCell generic, which should return a vector of the same length as the subset of the column passed to it. This vector is then placed into a data.frame and converted to text with format. Thus, each element of the vector should be some simple, usually character, representation of the corresponding element in the column.

Constructor

DataFrame(..., row.names = NULL, check.names = TRUE, stringsAsFactors): Constructs a DataFrame in similar fashion to data.frame. Each argument in ... is coerced to a DataFrame and combined column-wise. The row names should be given in row.names; otherwise, they are inherited from the arguments, as in data.frame. Explicitly passing NULL to row.names ensures that there are no rownames. If check.names is TRUE, the column names will be checked for syntactic validity and made unique, if necessary.

To store an object of a class that does not support coercion to DataFrame, wrap it in I(). The class must still have methods for length and []

The stringsAsFactors argument is ignored. The coercion of column arguments to DataFrame determines whether strings become factors.

make_zero_col_DFrame(nrow): Constructs a zero-column DFrame object with nrow rows. Intended for developers to use in other packages and typically not needed by the end user.

Accessors

In the following code snippets, x is a DataFrame.

dim(x): Get the length two integer vector indicating in the first and second element the number of rows and columns, respectively.

dimnames(x), dimnames(x) <- value: Get and set the two element list containing the row names (character vector of length nrow(x) or NULL) and the column names (character vector of length ncol(x)).
**DataFrame-class**

**Coercion**

`as(from, "DataFrame")`: By default, constructs a new DataFrame with `from` as its only column. If `from` is a matrix or data.frame, all of its columns become columns in the new DataFrame. If `from` is a list, each element becomes a column, recycling as necessary. Note that for the DataFrame to behave correctly, each column object must support element-wise subsetting via the `[]` method and return the number of elements with `length`. It is recommended to use the DataFrame constructor, rather than this interface.

`as.list(x)`: Coerces `x`, a DataFrame, to a list.

`as.data.frame(x, row.names=NULL, optional=FALSE)`: Coerces `x`, a DataFrame, to a data.frame. Each column is coerced to a data.frame and then column bound together. If `row.names` is `NULL`, they are retrieved from `x`, if it has any. Otherwise, they are inferred by the data.frame constructor.

NOTE: conversion of `x` to a data.frame is not supported if `x` contains any list, SimpleList, or CompressedList columns.

`as(from, "data.frame")`: Coerces a DataFrame to a data.frame by calling `as.data.frame(from)`.

`as.matrix(x)`: Coerces the DataFrame to a matrix, if possible.

`as.env(x, enclos = parent.frame())`: Creates an environment from `x` with a symbol for each `colnames(x)`. The values are not actually copied into the environment. Rather, they are dynamically bound using `makeActiveBinding`. This prevents unnecessary copying of the data from the external vectors into R vectors. The values are cached, so that the data is not copied every time the symbol is accessed.

**Subsetting**

In the following code snippets, `x` is a DataFrame.

`x[i, j, drop]`: Behaves very similarly to the `[.data.frame method, except `i` can be a logical Rle object and subsetting by matrix indices is not supported. Indices containing NA's are also not supported.

`x[i, j] <- value`: Behaves very similarly to the `[<-.data.frame method.

`x[[i]]`: Behaves very similarly to the `[[.data.frame method, except arguments `j` and `exact` are not supported. Column name matching is always exact. Subsetting by matrices is not supported.

`x[[i]] <- value`: Behaves very similarly to the `[[<-.data.frame method, except argument `j` is not supported.

**Displaying**

The `show()` method for DataFrame objects obeys global options `showHeadLines` and `showTaillines` for controlling the number of head and tail rows to display. See `?get_showHeadlines` for more information.

**Author(s)**

Michael Lawrence

- `get_showHeadLines` for controlling the number of DataFrame rows to display.

Examples

```r
score <- c(1L, 3L, NA)
counts <- c(10L, 2L, NA)
row.names <- c("one", "two", "three")

df <- DataFrame(score)  # single column
df["score"]
df <- DataFrame(score, row.names = row.names)  # with row names
rownames(df)

df <- DataFrame(vals = score)  # explicit naming
df["vals"]

# arrays
ary <- array(1:4, c(2,1,2))
sw <- DataFrame(I(ary))

# a data.frame
sw <- DataFrame(swiss)
as.data.frame(sw)  # swiss, without row names
# now with row names
sw <- DataFrame(swiss, row.names = rownames(swiss))
as.data.frame(sw)  # swiss

# subsetting
sw[]  # identity subset
sw[,]  # same

sw[NULL]  # no columns
sw[,NULL]  # no columns
sw[NULL,]  # no rows

## select columns
sw[1:3]
sw[,1:3]  # same as above
sw[,"Fertility"]
sw[,c(TRUE, FALSE, FALSE, FALSE, FALSE, FALSE)]

## select rows and columns
sw[4:5, 1:3]
```
**DataFrame-combine**

Combine DataFrame objects along their rows or columns, or merge them

---

**Description**

Various methods are provided to combine DataFrame objects along their rows or columns, or to merge them.

**Details**

In the code snippets below, all the input objects are expected to be DataFrame objects.
**DataFrame-combine**

`rbind(...)`: Creates a new DataFrame object by aggregating the rows of the input objects. Very similar to `rbind.data.frame()`, except in the handling of row names. If all elements have row names, they are concatenated and made unique. Otherwise, the result does not have row names. The returned DataFrame object inherits its metadata and metadata columns from the first input object.

`cbind(...)`: Creates a new DataFrame object by aggregating the columns of the input objects. Very similar to `cbind.data.frame()`. The returned DataFrame object inherits its metadata from the first input object. The metadata columns of the returned DataFrame object are obtained by combining the metadata columns of the input object with `combineRows()`.

`combineRows(x, ...)`: `combineRows()` is a generic function documented in the man page for `RectangularData` objects (see `?RectangularData`). The method for DataFrame objects behaves as documented in that man page.

`combineCols(x, ..., use.names=TRUE)`: `combineCols()` is a generic function documented in the man page for `RectangularData` objects (see `?RectangularData`). The method for DataFrame objects behaves as documented in that man page.

`combineUniqueCols(x, ..., use.names=TRUE)`: This function is documented in the man page for `RectangularData` objects (see `?RectangularData`).

`merge(x, y, ...)`: Merges two DataFrame objects `x` and `y`, with arguments in `...` being the same as those allowed by the base `merge()`. It is allowed for either `x` or `y` to be a `data.frame`.

**Examples**

```r
## ---------------------------------------------------------------------
## rbind()
## ---------------------------------------------------------------------
x1 <- DataFrame(A=1:5, B=letters[1:5], C=11:15)
y1 <- DataFrame(B=c(FALSE, NA, TRUE), C=c(FALSE, NA, TRUE), A=101:103)
rbind(x1, y1)

x2 <- DataFrame(A=Rle(101:103, 3:1), B=Rle(51:52, c(1, 5)))
y2 <- DataFrame(A=runif(2), B=Rle(c("a", "b"))
rbind(x2, y2)

## ---------------------------------------------------------------------
## combineRows()
## ---------------------------------------------------------------------
x3 <- DataFrame(A=1:3, B=letters[1:3], C=11:15)
y3 <- DataFrame(B=c(FALSE, NA, TRUE), C=c(FALSE, NA, TRUE), A=101:103)
combineRows(x3, y3)
```
y3 <- DataFrame(A=runif(2))
combineRows(x2, y3)

y4 <- DataFrame(B=Rle(c("a", "b")), C=runif(2))
combineRows(x2, y4)
combineRows(y4, x2)
combineRows(y4, x2, DataFrame(D=letters[1:3], B=301:303))

X <- DataFrame(x=1)
Y <- DataFrame(y="A")
Z <- DataFrame(z=TRUE)

combineCols(X, Y, Z, use.names=FALSE)

Y <- DataFrame(y=LETTERS[1:2])
rownames(X) <- "foo"
rownames(Y) <- c("foo", "bar")
rownames(Z) <- "bar"

combineCols(X, Y, Z)

X <- DataFrame(x=1)
Y <- DataFrame(y=LETTERS[1:2], dup=1:2)
Z <- DataFrame(z=TRUE, dup=2L)

rownames(X) <- "foo"
rownames(Y) <- c("foo", "bar")
rownames(Z) <- "bar"

combineUniqueCols(X, Y, Z)

Z$dup <- 3
combineUniqueCols(X, Y, Z)

x6 <- DataFrame(key=c(155, 2, 33, 17, 2, 26, 1), aa=1:7)
y6 <- DataFrame(key=1:26, bb=LETTERS)
merge(x6, y6, by="key")
merge(x6, y6, by="key", all.x=TRUE)
**Description**

The `DataFrame` class provides methods to compare across rows of the `DataFrame`, including ordering and matching. Each `DataFrame` is effectively treated as a vector of rows.

**Usage**

```r
## S4 method for signature 'DataFrame'
sameAsPreviousROW(x)

## S4 method for signature 'DataFrame,DataFrame'
match(x, table, nomatch = NA_integer_, incomparables = NULL, ...)

## S4 method for signature 'DataFrame'
order(..., na.last = TRUE, decreasing = FALSE, method = c("auto", "shell", "radix"))

## S4 method for signature 'DataFrame,DataFrame'
pcompare(x, y)

## S4 method for signature 'DataFrame,DataFrame'
e1 == e2

## S4 method for signature 'DataFrame,DataFrame'
e1 <= e2
```

**Arguments**

- `x, table, y, e1, e2`
  A `DataFrame` object.
- `nomatch, incomparables`
  See `?base::match`.
- `...`
  For `match`, further arguments to pass to `match`.
  For `order`, one or more `DataFrame` objects.
- `decreasing, na.last, method`
  See `?base::order`.

**Details**

The treatment of a `DataFrame` as a “vector of rows” is useful in many cases, e.g., when each row is a record that needs to be ordered or matched. The methods provided here allow the use of all methods described in `?Vector-comparison`, including sorting, matching, de-duplication, and so on.
Careful readers will notice this behaviour differs from the usual semantics of a `data.frame`, which acts as a list-like vector of columns. This discrepancy rarely causes problems, as it is not particularly common to compare columns of a `data.frame` in the first place.

Note that a match method for `DataFrame` objects is explicitly defined to avoid calling the corresponding method for `List` objects, which would yield the (undesired) list-like semantics. The same rationale is behind the explicit definition of `<=` and `==` despite the availability of `pcompare`.

**Value**

For `sameAsPreviousROW`: see `sameAsPreviousROW`.

For `match`: see `match`.

For `order`: see `order`.

For `pcompare`, `==` and `<=`: see `pcompare`.

**Author(s)**

Aaron Lun

**Examples**

```r
# Mocking up a DataFrame.
DF <- DataFrame(
  A=sample(LETTERS, 100, replace=TRUE),
  B=sample(5, 100, replace=TRUE)
)

# Matching:
match(DF, DF[1:10,])
selmatch(DF)
unique(DF)

# Ordering, alone and with other vectors:
sort(DF)
order(DF, runif(nrow(DF)))

# Parallel comparison:
DF==DF
DF==DF[1,]
```

**Description**

Common operations on `DataFrame` objects.
Splitting

In the code snippet below, `x` is a `DataFrame` object.

```r
split(x, f, drop = FALSE)
```

Splits `x` into a `SplitDataFrameList` object, according to `f`, dropping elements corresponding to unrepresented levels if `drop` is `TRUE`.

Looping

In the code snippet below, `x` is a `DataFrame` object.

```r
by(data, INDICES, FUN, ..., simplify = TRUE)
```

Apply `FUN` to each group of data, a `DataFrame`, formed by the factor (or list of factors) `INDICES`. Exactly the same contract as `as.data.frame`.

Subsetting based on NA content

In the code snippets below, `x` is a `DataFrame` object.

```r
na.omit(object)
```

Returns a subset with incomplete cases removed.

```r
na.exclude(object)
```

Returns a subset with incomplete cases removed (but to be included with NAs in statistical results).

```r
is.na(x)
```

Returns a logical matrix indicating which cells are missing.

```r
complete.cases(x)
```

Returns a logical vector identifying which cases have no missing values.

Transforming

In the code snippet below, `x` is a `DataFrame` object.

```r
transform('_data', ...)
```

Adds or replaces columns based on expressions in `...`. See `transform`.

Statistical modeling with DataFrame

A number of wrappers are implemented for performing statistical procedures, such as model fitting, with `DataFrame` objects.

Tabulation:

```r
xtabs(formula = ~., data, subset, na.action, exclude = c(NA, NaN), drop.unused.levels = FALSE)
```

Like the original `xtabs`, except `data` is a `DataFrame`.

Author(s)

Michael Lawrence

- `by` in the `base` package.
- `na.omit` in the `stats` package.
- `transform` in the `base` package.
- `xtabs` in the `stats` package.
- `splitAsList` in this package (S4Vectors).
• SplitDataFrameList objects in the IRanges package.
• DataFrame objects.

Examples

```r
## split
sw <- DataFrame(swiss)
swsplit <- split(sw, sw[["Education"]])

## rbind & cbind
do.call(rbind, as.list(swsplit))
cbind(DataFrame(score), DataFrame(counts))

df <- DataFrame(as.data.frame(UCBAdmissions))
xtabs(Freq ~ Gender + Admit, df)
```

---

### Description

The DataFrameFactor class is a subclass of the Factor class where the levels are the rows of a DataFrame. It provides a few methods to mimic the behavior of an actual DataFrame while retaining the memory efficiency of the Factor structure.

### Usage

```r
DataFrameFactor(x, levels, index=NULL, ...) # constructor function
```

### Arguments

- **x, levels**  
  DataFrame objects. At least one of x and levels must be specified. If index is NULL, both can be specified.
  
  When levels is specified, it must be a DataFrame with no duplicate rows (i.e. anyDuplicated(levels) must return 0).
  
  See ?Factor for more details.

- **index**  
  NULL or an integer (or numeric) vector of valid positive indices (no NAs) into levels. See ?Factor for details.

- **...**  
  Optional metadata columns.

### Value

A DataFrameFactor object.
Accessors

DataFrameFactor objects support the same set of accessors as Factor objects. In addition, it mimics some aspects of the DataFrame interface. The general principle is that, for these methods, a DataFrameFactor \( x \) behaves like the expanded DataFrame \( \text{unfactor}(x) \).

- \( x\$\text{name} \) will return column name from \( \text{levels}(x) \) and expand it according to the indices in \( x \).
- \( x[i, j, \ldots, \text{drop=}\text{TRUE}] \) will return a new DataFrameFactor subsetted to entries \( i \), where the levels are subsetted by column to contain only columns \( j \). If the resulting levels only have one column and \( \text{drop=}\text{TRUE} \), the expanded values of the column are returned directly.
- \( \text{dim}(x) \) will return the length of the DataFrameFactor and the number of columns in its levels.
- \( \text{dimnames}(x) \) will return the names of the DataFrameFactor and the column names in its levels.

Caution

The DataFrame-like methods implemented here are for convenience only. Users should not assume that the DataFrameFactor complies with other aspects of the DataFrame interface, due to fundamental differences between a DataFrame and the Factor parent class, e.g., in the interpretation of their “length”. Outside of the methods listed above, the DataFrameFactor is not guaranteed to work as a drop-in replacement for a DataFrame - use \( \text{unfactor}(x) \) instead.

Author(s)

Aaron Lun

See Also

Factor objects for the parent class.

Examples

df <- DataFrame(X=sample(5, 100, replace=TRUE), Y=sample(c("A","B"), 100, replace=TRUE))
dffac <- DataFrameFactor(df)
dffac

dffac$X
dffac[,c("Y","X")]
dffac[1:10,"X"]
colnames(dffac)

# The usual Factor methods may also be used:
unfactor(dffac)
levels(dffac)
as.integer(dffac)
Unlist the list-like columns of a DataFrame object

Description
expand transforms a DataFrame object into a new DataFrame object where the columns specified by the user are unlisted. The transformed DataFrame object has the same colnames as the original but typically more rows.

Usage
## S4 method for signature 'DataFrame'
expand(x, colnames, keepEmptyRows = FALSE, recursive = TRUE)

Arguments
x 
A DataFrame object with list-like columns or a Vector object with list-like metadata columns (i.e. with list-like columns in mcols(x)).

colnames 
A character or numeric vector containing the names or indices of the list-like columns to unlist. The order in which columns are unlisted is controlled by the column order in this vector. This defaults to all of the recursive (list-like) columns in x.

keepEmptyRows 
A logical indicating if rows containing empty list elements in the specified colnames should be retained or dropped. When TRUE, list elements are replaced with NA and all rows are kept. When FALSE, rows with empty list elements in the colnames columns are dropped.

recursive 
If TRUE, expand each column recursively, with the result representing their cartesian product. If FALSE, expand all of the columns in parallel, which requires that they all share the same skeleton.

Value
A DataFrame object that has been expanded row-wise to match the length of the unlisted columns.

See Also
• DataFrame objects.

Examples
library(IRanges)
aa <- CharacterList("a", paste0("d", 1:2), paste0("b", 1:3), c(), "c")
bb <- CharacterList(paste0("sna", 1:2), "foo", paste0("bar",1:3),c(),"hica")
df <- DataFrame(aa=aa, bb=bb, cc=11:15)

## Expand by all list-like columns (aa, bb), dropping rows with empty
## list elements:
```
expand(df)

## Expand the aa column only:
expand(df, colnames="aa", keepEmptyRows=TRUE)
expand(df, colnames="aa", keepEmptyRows=FALSE)

## Expand the aa and then the bb column:
expand(df, colnames=c("aa","bb"), keepEmptyRows=TRUE)
expand(df, colnames=c("aa","bb"), keepEmptyRows=FALSE)

## Expand the aa and dd column in parallel:
df$dd <- relist(seq_along(unlist(aa)), aa)
expand(df, colnames=c("aa","dd"), recursive=FALSE)
```

---

### Factor-class

**Factor objects**

#### Description

The Factor class serves a similar role as `factor` in base R (a.k.a. ordinary factor) except that the levels of a Factor object can be *any vector-like object*, that is, they can be an ordinary vector or a `Vector` derivative, or even an ordinary factor or another Factor object.

A notable difference with ordinary factors is that Factor objects cannot contain NAs, at least for now.

#### Usage

```r
Factor(x, levels, index=NULL, ...) # constructor function
```

#### Arguments

- `x, levels` At least one of `x` and `levels` must be specified. If `index` is `NULL`, both can be specified.
  - When `levels` is specified, it must be a *vector-like object* (see above) with no duplicates (i.e. `anyDuplicated(levels)` must return 0).
  - When `x` and `levels` are both specified, they should typically have the same class (or, at least, `match(x, levels)` must work on them), and all the elements in `x` must be represented in `levels` (i.e. the integer vector returned by `match(x, levels)` should contain no NAs). See Details section below.

- `index` `NULL` or an integer (or numeric) vector of valid positive indices (no NAs) into `levels`. See Details section below.

- `...` Optional metadata columns.

#### Details

There are 4 different ways to use the `Factor()` constructor function:
1. Factor(x, levels) (i.e. index is missing): In this case match(x, levels) is used internally to encode x as a Factor object. An error is returned if some elements in x cannot be matched to levels so it's important to make sure that all the elements in x are represented in levels when doing Factor(x, levels).

2. Factor(x) (i.e. levels and index are missing): This is equivalent to Factor(x, levels=unique(x)).

3. Factor(levels=levels, index=index) (i.e. x is missing): In this case the encoding of the Factor object is supplied via index, that is, index must be an integer (or numeric) vector of valid positive indices (no NAs) into levels. This is the most efficient way to construct a Factor object.

4. Factor(levels=levels) (i.e. x and index are missing): This is a convenient way to construct a 0-length Factor object with the specified levels. In other words, it's equivalent to Factor(levels=levels, index=integer(0)).

Value
A Factor object.

Accessors
Factor objects support the same set of accessors as ordinary factors. That is:

- length(x) to get the length of Factor object x.
- names(x) and names(x) <- value to get and set the names of Factor object x.
- levels(x) and levels(x) <- value to get and set the levels of Factor object x.
- nlevels(x) to get the number of levels of Factor object x.
- as.integer(x) to get the encoding of Factor object x. Note that length(as.integer(x)) and names(as.integer(x)) are the same as length(x) and names(x), respectively.

In addition, because Factor objects are Vector derivatives, they support the mcols() and metadata() getters and setters.

Decoding a Factor
unfactor(x) can be used to decode Factor object x. It returns an object of the same class as levels(x) and same length as x. Note that it is the analog of as.character() on ordinary factors, with the notable difference that unfactor(x) propagates the names on x.

For convenience, unfactor(x) also works on ordinary factor x.
unfactor() supports extra arguments use.names and ignore.mcols to control whether the names and metadata columns on the Factor object to decode should be propagated or not. By default they are propagated, that is, the default values for use.names and ignore.mcols are TRUE and FALSE, respectively.

Coercion
From vector or Vector to Factor: coercion of a vector-like object x to Factor is supported via as(x, "Factor") and is equivalent to Factor(x). There are 2 IMPORTANT EXCEPTIONS to this:
1. If x is an ordinary factor, as(x, "Factor") returns a Factor with the same levels, encoding, and names, as x. Note that after coercing an ordinary factor to Factor, going back to factor again (with as.factor()) restores the original object with no loss.

2. If x is a Factor object, as(x, "Factor") is either a no-op (when x is a Factor instance), or a demotion to Factor (when x is a Factor derivative like GRangesFactor).

From Factor to integer: as.integer(x) is supported on Factor object x and returns its encoding (see Accessors section above).

From Factor to factor: as.factor(x) is supported on Factor object x and returns an ordinary factor where the levels are as.character(levels(x)).

From Factor to character: as.character(x) is supported on Factor object x and is equivalent to unfactor(as.factor(x)), which is also equivalent to as.character(unfactor(x)).

**Subsetting**

A Factor object can be subsetted with [, like an ordinary factor.

**Concatenation**

2 or more Factor objects can be concatenated with c(). Note that, unlike with ordinary factors, c() on Factor objects preserves the class i.e. it returns a Factor object. In other words, c() acts as an endomorphism on Factor objects.

The levels of c(x, y) are obtained by appending to levels(x) the levels in levels(y) that are "new" i.e. that are not already in levels(x).

append(), which is implemented on top of c(), also works on Factor objects.

**Comparing & Ordering**

Factor objects support comparing (e.g. ==, !=, <=, <, match()) and ordering (e.g. order(), sort(), rank()) operations. All these operations behave like they would on the unfactored versions of their operands.

For example F1 <= F2, match(F1, F2), and sort(F1), are equivalent to unfactor(F1) <= unfactor(F2), match(unfactor(F1), unfactor(F2)), and sort(unfactor(F1)), respectively.

Examples

```r
showClass("Factor")  # Factor extends Vector

## -----------------------------------------------
## CONSTRUCTOR & ACCESSORS
## -----------------------------------------------
library(IRanges)
set.seed(123)
ir0 <- IRanges(sample(5, 8, replace=TRUE), width=10,
                names=letters[1:8], ID=paste0("ID", 1:8))

## Use explicit levels:
ir1 <- IRanges(1:6, width=10)
F1 <- Factor(ir0, levels=ir1)
F1
length(F1)
names(F1)
levels(F1)  # ir1
nlevels(F1)
as.integer(F1)  # encoding

## If we don't specify the levels, they'll be set to unique(ir0):
F2 <- Factor(ir0)
F2
length(F2)
names(F2)
levels(F2)  # unique(ir0)
nlevels(F2)
as.integer(F2)

## -----------------------------------------------
## DECODING
## -----------------------------------------------
unfactor(F1)

stopifnot(identical(ir0, unfactor(F1)))
stopifnot(identical(ir0, unfactor(F2)))

unfactor(F1, use.names=FALSE)
unfactor(F1, ignore.mcols=TRUE)

## -----------------------------------------------
## COERCION
## -----------------------------------------------
F2b <- as(ir0, "Factor")  # same as Factor(ir0)
stopifnot(identical(F2, F2b))

as.factor(F2)
as.factor(F1)

as.character(F1)  # same as unfactor(as.factor(F1)),

# and also same as as.character(unfactor(F1))
```
## On an ordinary factor 'f', 'as(f, "Factor")' and 'Factor(f)' are
## NOT the same:

```r
f <- factor(sample(letters, 500, replace=TRUE), levels=letters)
as(f, "Factor") # same levels as 'f'
Factor(f)       # levels **are** 'f'!
```

```r
stopifnot(identical(f, as.factor(as(f, "Factor"))))
```

## CONCATENATION

```r
ir3 <- IRanges(c(5, 2, 8:6), width=10)
F3 <- Factor(levels=ir3, index=2:4)
F13 <- c(F1, F3)
F13
levels(F13)
```

```r
stopifnot(identical(c(unfactor(F1), unfactor(F3)), unfactor(F13)))
```

## COMPARING & ORDERING

```r
F1 == F2 # same as unfactor(F1) == unfactor(F2)
order(F1) # same as order(unfactor(F1))
order(F2) # same as order(unfactor(F2))
```

```r
# The levels of the Factor influence the order of the table:
table(F1)
table(F2)
```

---

### FilterMatrix-class

**Matrix for Filter Results**

#### Description

A FilterMatrix object is a matrix meant for storing the logical output of a set of FilterRules, where each rule corresponds to a column. The FilterRules are stored within the FilterMatrix object, for the sake of provenance. In general, a FilterMatrix behaves like an ordinary matrix.

#### Accessor methods

In the code snippets below, `x` is a FilterMatrix object.

- `filterRules(x)`: Get the FilterRules corresponding to the columns of the matrix.

#### Constructor

- `FilterMatrix(matrix, filterRules)`: Constructs a FilterMatrix, from a given matrix and filterRules. Not usually called by the user, see `evalSeparately`.
FilterRules-class

Utilities

summary(object, discarded = FALSE, percent = FALSE): Returns a numeric vector containing the total number of records (nrow), the number passed by each filter, and the number of records that passed every filter. If discarded is TRUE, then the numbers are inverted (i.e., the values are subtracted from the number of rows). If percent is TRUE, then the numbers are percent of total.

• FilterRules objects.

FilterRules-class

Collection of Filter Rules

Description

A FilterRules object is a collection of filter rules, which can be either expression or function objects. Rules can be disabled/enabled individually, facilitating experimenting with different combinations of filters.

Details

It is common to split a dataset into subsets during data analysis. When data is large, however, representing subsets (e.g. by logical vectors) and storing them as copies might become too costly in terms of space. The FilterRules class represents subsets as lightweight expression and/or function objects. Subsets can then be calculated when needed (on the fly). This avoids copying and storing a large number of subsets. Although it might take longer to frequently recalculate a subset, it often is a relatively fast operation and the space savings tend to be more than worth it when data is large.

Rules may be either expressions or functions. Evaluating an expression or invoking a function should result in a logical vector. Expressions are often more convenient, but functions (i.e. closures) are generally safer and more powerful, because the user can specify the enclosing environment. If a rule is an expression, it is evaluated inside the envir argument to the eval method (see below). If a function, it is invoked with envir as its only argument. See examples.

Accessor methods

In the code snippets below, x is a FilterRules object.

active(x): Get the logical vector of length length(x), where TRUE for an element indicates that the corresponding rule in x is active (and inactive otherwise). Note that names(active(x)) is equal to names(x).
active(x) <- value: Replace the active state of the filter rules. If value is a logical vector, it should be of length length(x) and indicate which rules are active. Otherwise, it can be either numeric or character vector, in which case it sets the indicated rules (after dropping NA's) to active and all others to inactive. See examples.

Constructor

FilterRules(exprs = list(), ..., active = TRUE): Constructs a FilterRules with the rules given in the list exprs or in .... The initial active state of the rules is given by active, which is recycled as necessary. Elements in exprs may be either character (parsed into an expression), a language object (coerced to an expression), an expression, or a function that takes at least one argument. IMPORTANTLY, all arguments in ... are quote(’d and then coerced to an expression. So, for example, character data is only parsed if it is a literal.

The names of the filters are taken from the names of exprs and ..., if given. Otherwise, the character vectors take themselves as their name and the others are deparsed (before any coercion). Thus, it is recommended to always specify meaningful names. In any case, the names are made valid and unique.

Subsetting and Replacement

In the code snippets below, x is a FilterRules object.

x[i]: Subsets the filter rules using the same interface as for Vector.

x[[i]]: Extracts an expression or function via the same interface as for List.

x[[i]] <- value: The same interface as for List. The default active state for new rules is TRUE.

Concatenation

In the code snippets below, x is a FilterRules object.

x & y: Appends the rules in y to the rules in x.

c(x, ..., recursive = FALSE): Concatenates the FilterRule instances in ... onto the end of x.

append(x, values, after = length(x)): Appends the values FilterRules instance onto x at the index given by after.

Evaluating

eval(expr, envir = parent.frame(), enclos = if (is.list(envir) || is.pairlist(envir)) parent.frame() else baseenv()):

Evaluates a FilterRules instance (passed as the expr argument). Expression rules are evaluated in envir, while function rules are invoked with envir as their only argument. The evaluation of a rule should yield a logical vector. The results from the rule evaluations are combined via the AND operation (i.e. & ) so that a single logical vector is returned from eval.

evalSeparately(expr, envir = parent.frame(), enclos = if (is.list(envir) || is.pairlist(envir)) parent.frame() else baseenv()):

Evaluates separately each rule in a FilterRules instance (passed as the expr argument). Expression rules are evaluated in envir, while function rules are invoked with envir as their only argument. The evaluation of a rule should yield a logical vector. The results from the rule evaluations are combined into a logical matrix, with a column for each rule. This is essentially the parallel evaluator, while eval is the serial evaluator.
subsetByFilter(x, filter): Evaluates filter on x and uses the result to subset x. The result contains only the elements in x for which filter evaluates to TRUE.

summary(object, subject): Returns an integer vector with the number of elements in subject that pass each rule in object, along with a count of the elements that pass all filters.

Filter Closures
When a closure (function) is included as a filter in a FilterRules object, it is converted to a FilterClosure, which is currently nothing more than a marker class that extends function. When a FilterClosure filter is extracted, there are some accessors and utilities for manipulating it:

params: Gets a named list of the objects that are present in the enclosing environment (without inheritance). This assumes that a filter is constructed via a constructor function, and the objects in the frame of the constructor (typically, the formal arguments) are the parameters of the filter.

Author(s)
Michael Lawrence

See Also
FilterMatrix objects for storing the logical output of a set of FilterRules objects.

Examples
## constructing a FilterRules instance

```r
## an empty set of filters
filters <- FilterRules()

## as a simple character vector
filts <- c("peaks", "promoters")
filters <- FilterRules(filts)
active(filters) # all TRUE

## with functions and expressions
filts <- list(under_peaks = expression(peaks), promoters = expression(promoters),
             find_eboxes = function(rd) rep(FALSE, nrow(rd)))
filters <- FilterRules(filts, active = FALSE)
active(filters) # all FALSE

## direct, quoted args (character literal parsed)
filters <- FilterRules(under_peaks = peaks, in_promoters = "promoters")
filts <- list(under_peaks = expression(peaks),
             in_promoters = expression(promoters))

## specify both exprs and additional args
filters <- FilterRules(filts, diffexp = de)
filts <- c("promoters", "peaks", "introns")
filters <- FilterRules(filts)
```
## evaluation

df <- DataFrame(peaks = c(TRUE, TRUE, FALSE, FALSE),
    promoters = c(TRUE, FALSE, FALSE, TRUE),
    introns = c(TRUE, FALSE, FALSE, FALSE))
eval(filters, df)
fm <- evalSeparately(filters, df)
identical(filterRules(fm), filters)
summary(fm)
summary(fm, percent = TRUE)
fm <- evalSeparately(filters, df, serial = TRUE)

## set the active state directly

active(filters) <- FALSE  # all FALSE
active(filters) <- TRUE  # all TRUE
active(filters) <- c(FALSE, FALSE, TRUE)  # use a filter name

## toggle the active state by name or index

active(filters) <- c(NA, 2)  # NA's are dropped
active(filters) <- c("peaks", NA)

---

### Hits-class

Hits objects

**Description**

The Hits class is a container for representing a set of hits between a set of left nodes and a set of right nodes. Note that only the hits are stored in the object. No information about the left or right nodes is stored, except their number.

For example, the `findOverlaps` function, defined and documented in the `IRanges` package, returns the hits between the query and subject arguments in a Hits object.

**Usage**

```r
## Constructor functions

Hits(from=integer(0), to=integer(0), nLnode=0L, nRnode=0L, ..., sort.by.query=FALSE)
SelfHits(from=integer(0), to=integer(0), nnode=0L, ..., sort.by.query=FALSE)
```

**Arguments**

- `from, to` 2 integer vectors of the same length. The values in `from` must be >= 1 and <= `nLnode`. The values in `to` must be >= 1 and <= `nRnode`. 

---
**Hits-class**

- **nLnode, nRnode**: Number of left and right nodes.
- ...: Metadata columns to set on the Hits object. All the metadata columns must be vector-like objects of the same length as from and to.
- **sort.by.query**: Should the hits in the returned object be sorted by query? If yes, then a SortedByQueryHits object is returned (SortedByQueryHits is a subclass of Hits).
- **nnode**: Number of nodes.

**Accessors**

In the code snippets below, x is a Hits object.

- **length(x)**: get the number of hits
- **from(x)**: Equivalent to as.data.frame(x)[[1]].
- **to(x)**: Equivalent to as.data.frame(x)[[2]].
- **nLnode(x), nrow(x)**: get the number of left nodes
- **nRnode(x), ncol(x)**: get the number of right nodes
- **countLnodeHits(x)**: Counts the number of hits for each left node, returning an integer vector.
- **countRnodeHits(x)**: Counts the number of hits for each right node, returning an integer vector.

The following accessors are just aliases for the above accessors:

- **queryHits(x)**: alias for from(x).
- **subjectHits(x)**: alias for to(x).
- **queryLength(x)**: alias for nLnode(x).
- **subjectLength(x)**: alias for nRnode(x).
- **countQueryHits(x)**: alias for countLnodeHits(x).
- **countSubjectHits(x)**: alias for countRnodeHits(x).

**Coercion**

In the code snippets below, x is a Hits object.

- **as.matrix(x)**: Coerces x to a two column integer matrix, with each row representing a hit between a left node (first column) and a right node (second column).
- **as.table(x)**: Counts the number of hits for each left node in x and outputs the counts as a table.
- **as(x, "DataFrame")**: Creates a **DataFrame** by combining the result of as.matrix(x) with mcols(x).
- **as.data.frame(x)**: Attempts to coerce the result of as(x, "DataFrame") to a data.frame.

**Subsetting**

In the code snippets below, x is a Hits object.

- **x[i]**: Return a new Hits object made of the elements selected by i.
- **x[i, j]**: Like the above, but allow the user to conveniently subset the metadata columns thru j.
- **x[i] <- value**: Replacement version of x[i].

See `?`[`` in this package (the **S4Vectors** package) for more information about subsetting Vector derivatives and for an important note about the `x[i, j]` form.
**Concatenation**

\( \text{c}(x, \ldots, \text{ignore.mcols=FALSE}) \): Concatenate Hits object \( x \) and the Hits objects in \(... \) together.

See \?c in this package (the \texttt{S4Vectors} package) for more information about concatenating Vector derivatives.

**Other transformations**

In the code snippets below, \( x \) is a Hits object.

\( \text{t}(x) \): Transpose \( x \) by interchanging the left and right nodes. This allows, for example, counting the number of hits for each right node using \texttt{as.table}.

\texttt{remapHits}(\( x, \text{Lnodes.remapping=NULL, new.nLnode=} \text{NA, Rnodes.remapping=} \text{NULL, new.nRnode=} \text{NA}) \): Only supports SortedByQueryHits objects at the moment.

Remaps the left and/or right nodes in \( x \). The left nodes are remapped thru the map specified via the \texttt{Lnodes.remapping} and \texttt{new.nLnode} arguments. The right nodes are remapped thru the map specified via the \texttt{Rnodes_remapping} and \texttt{new.nRnode} arguments.

\texttt{Lnodes.remapping} must represent a function defined on the \( 1..M \) interval that takes values in the \( 1..N \) interval, where \( N = \text{nLnode}(x) \) and \( M \) is the value specified by the user via the \texttt{new.nLnode} argument. Note that this mapping function doesn’t need to be injective or surjective. Also it is not represented by an R function but by an integer vector of length \( M \) with no NAs. More precisely \texttt{Lnodes.remapping} can be NULL (identity map), or a vector of \( \text{nLnode}(x) \) non-NA integers that are \( \geq 1 \) and \( \leq \text{new.nLnode} \), or a factor of length \( \text{nLnode}(x) \) with no NAs (a factor is treated as an integer vector, and, if missing, \texttt{new.nLnode} is taken to be its number of levels). Note that a factor will typically be used to represent a mapping function that is not injective.

The same applies to the \texttt{Rnodes_remapping}.

\texttt{remapHits} returns a Hits object where \texttt{from}(\( x \)) and \texttt{to}(\( x \)) have been remapped thru the 2 specified maps. This remapping is actually only the 1st step of the transformation, and is followed by 2 additional steps: (2) the removal of duplicated hits, and (3) the reordering of the hits (first by query hits, then by subject hits). Note that if the 2 maps are injective then the remapping won’t introduce duplicated hits, so, in that case, step (2) is a no-op (but is still performed). Also if the "query map" is strictly ascending and the "subject map" ascending then the remapping will preserve the order of the hits, so, in that case, step (3) is also a no-op (but is still performed).

\texttt{breakTies}(\( x, \text{method=} \text{c("first", "last"), rank}) \): Restrict the hits so that every left node maps to at most one right node. If \texttt{method} is "first", for each left node, select the edge with the first (lowest rank) right node, if any. If \texttt{method} is "last", select the edge with the last (highest rank) right node. If \texttt{rank} is not missing, it should be a formula specifying an alternative ranking according to its terms (see \texttt{rank}).

**SelfHits**

A SelfHits object is a Hits object where the left and right nodes are identical. For a SelfHits object \( x \), \( \text{nLnode}(x) \) is equal to \( \text{nRnode}(x) \). The object can be seen as an oriented graph where \( \text{nLnode} \) is the nb of nodes and the hits are the (oriented) edges. SelfHits objects support the same set of accessors as Hits objects plus the \texttt{nnode()} accessor that is equivalent to \texttt{nLnode()} and \texttt{nRnode()}. We also provide two little utilities to operate on a SelfHits object \( x \):
isSelfHit(x): A self hit is an edge from a node to itself. isSelfHit(x) returns a logical vector parallel to x indicating which elements in x are self hits.

isRedundantHit(x): When there is more than 1 edge between 2 given nodes (regardless of orientation), the extra edges are considered to be redundant hits. isRedundantHit(x) returns a logical vector parallel to x indicating which elements in x are redundant hits.

Michael Lawrence and Hervé Pagès

See Also
- Hits-comparison for comparing and ordering hits.
- The findOverlaps function in the IRanges package which returns SortedByQueryHits object.
- Hits-examples in the IRanges package, for some examples of Hits object basic manipulation.
- setops-methods in the IRanges package, for set operations on Hits objects.

Examples
from <- c(5, 2, 3, 3, 3, 2)
to <- c(11, 15, 5, 4, 5, 11)
id <- letters[1:6]

Hits(from, to, 7, 15, id)

## selectHits()
## remapHits()
Hits-comparison

Description

==, !=, <=, >=, <, >, match(), %in%, order(), sort(), and rank() can be used on Hits objects to compare and order hits.

Note that only the "pcompare", "match", and "order" methods are actually defined for Hits objects. This is all what is needed to make all the other comparing and ordering operations (i.e. ==, !=, <=, >=, <, >, %in%, sort(), and rank()) work on these objects (see ?`Vector-comparison` for more information about this).

Usage

```
## S4 method for signature 'Hits,Hits'
pcompare(x, y)

## S4 method for signature 'Hits,Hits'
match(x, table, nomatch=NA_integer_, incomparables=NULL,
      method=c("auto", "quick", "hash"))

## S4 method for signature 'Hits'
order(..., na.last=TRUE, decreasing=FALSE, method=c("auto", "shell", "radix"))
```

Arguments

x, y, table

Compatible Hits objects, that is, Hits objects with the same subject and query lengths.
nomatch  The value to be returned in the case when no match is found. It is coerced to an integer.

incomparables  Not supported.

method  For match: Use a Quicksort-based (method="quick") or a hash-based (method="hash") algorithm. The latter tends to give better performance, except maybe for some pathological input that we've not encountered so far. When method="auto" is specified, the most efficient algorithm will be used, that is, the hash-based algorithm if length(x) <= 2^29, otherwise the Quicksort-based algorithm. For order: The method argument is ignored.

...  One or more Hits objects. The additional Hits objects are used to break ties.

na.last  Ignored.

decreasing  TRUE or FALSE.

Details

Only hits that belong to Hits objects with same subject and query lengths can be compared. Hits are ordered by query hit first, and then by subject hit. On a Hits object, order, sort, and rank are consistent with this order.

pcompare(x, y): Performs element-wise (aka "parallel") comparison of 2 Hits objects x and y, that is, returns an integer vector where the i-th element is less than, equal to, or greater than zero if x[i] is considered to be respectively less than, equal to, or greater than y[i]. See ?'Vector-comparison' for how x or y is recycled when the 2 objects don't have the same length.

match(x, table, nomatch=NA_integer_, method=c("auto", "quick", "hash")): Returns an integer vector of the length of x, containing the index of the first matching hit in table (or nomatch if there is no matching hit) for each hit in x.

order(...): Returns a permutation which rearranges its first argument (a Hits object) into ascending order, breaking ties by further arguments (also Hits objects).

Examples

```r
## A. ELEMENT-WISE (AKA "PARALLEL") COMPARISON OF 2 Hits OBJECTS

hits <- Hits(c(2, 4, 4, 4, 5, 5), c(3, 1, 3, 2, 3, 2), 6, 3)

hits
```
```r
pcompare(hits, hits[3])
pcompare(hits[3], hits)

hits == hits[3]
hits != hits[3]
hits >= hits[3]
hits < hits[3]

## ---------------------------------------------------------------------
## B. match(), %in%
## ---------------------------------------------------------------------
table <- hits[-c(1, 3)]
match(hits[-c(1, 3)], table)
hits %in% table

## ---------------------------------------------------------------------
## C. order(), sort(), rank()
## ---------------------------------------------------------------------
order(hits)
sort(hits)
rank(hits)
```

### Hits-setops

**Set operations on Hits objects**

#### Description

Perform set operations on **Hits** objects.

#### Details

union(x, y), intersect(x, y), setdiff(x, y), and setequal(x, y) work on **Hits** objects x and y only if the objects are *compatible Hits objects*, that is, if they have the same subject and query lengths. These operations return respectively the union, intersection, (asymmetric!) difference, and equality of the *sets* of hits in x and y.

#### Value

union returns a **Hits** object obtained by appending to x the hits in y that are not already in x.

intersect returns a **Hits** object obtained by keeping only the hits in x that are also in y.

setdiff returns a **Hits** object obtained by dropping from x the hits that are in y.

setequal returns TRUE if x and y contain the same *sets* of hits and FALSE otherwise.

union, intersect, and setdiff propagate the names and metadata columns of their first argument (x).
**HitsList-class**

- Hits objects.
- Hits-comparison for comparing and ordering hits.
- BiocGenerics::union, BiocGenerics::intersect, and BiocGenerics::setdiff in the BiocGenerics package for general information about these generic functions.

**Examples**

```r
x <- Hits(c(2, 4, 4, 4, 5, 5), c(3, 1, 3, 2, 3, 2), 6, 3,
          score=11:16)
x

y <- Hits(c(1, 3, 4, 4, 5, 5, 5), c(3, 3, 2, 1, 2, 1, 3), 6, 3,
          score=21:27)
y

union(x, y)  # same hits as in union(x, y), but in different order

union(y, x)  # same hits as in union(x, y), but in different order

intersect(x, y)
intersect(y, x)  # same hits as in intersect(x, y), but in different order

setdiff(x, y)
setdiff(y, x)

setequal(x, y)
```

---

**HitsList-class**

**List of Hits objects**

**Description**

The HitsList class stores a set of Hits objects. It’s typically used to represent the result of findOverlaps on two IntegerRangesList objects.

**Details**

Roughly the same set of utilities are provided for HitsList as for Hits:

The as.matrix method coerces a HitsList object in a similar way to Hits, except a column is prepended that indicates which space (or element in the query IntegerRangesList) to which the row corresponds.
The `as.table` method flattens or unlists the list, counts the number of hits for each query range and outputs the counts as a table, which has the same shape as from a single `Hits` object.

To transpose a `HitsList` object \(x\), so that the subject and query in each space are interchanged, call \(t(x)\). This allows, for example, counting the number of hits for each subject element using `as.table`.

**Accessors**

- `queryHits(x)`: Equivalent to `unname(as.matrix(x)[,1])`.
- `subjectHits(x)`: Equivalent to `unname(as.matrix(x)[,2])`.
- `space(x)`: gets the character vector naming the space in the query `IntegerRangesList` for each hit, or `NULL` if the query did not have any names.

**Coercion**

In the code snippets below, \(x\) is a `HitsList` object.

- `as.matrix(x)`: calls `as.matrix` on each `Hits`, combines them row-wise and offsets the indices so that they are aligned with the result of calling `unlist` on the query and subject.
- `as.table(x)`: counts the number of hits for each query element in \(x\) and outputs the counts as a table, which is aligned with the result of calling `unlist` on the query.
- `t(x)`: Interchange the query and subject in each space of \(x\), returns a transposed `HitsList` object.

**Note**

This class is highly experimental. It has not been well tested and may disappear at any time.

**Author(s)**

Michael Lawrence

**See Also**

- `findOverlaps` in the `IRanges` package, which returns a `HitsList` object when the query and subject are `IntegerRangesList` objects.

**Examples**

```r
hits <- Hits(rep(1:20, each=5), 100:1, 20, 100)
hlist <- splitAsList(hits, 1:5)
hlist
hlist[[1]]
hlist[[2]]

## Some sanity checks:

hits1 <- Hits(c(4, 4, 15, 15), c(1, 2, 3, 4), 20, 4)
hits2 <- Hits(c(4, 4, 15, 15), c(1, 2, 3, 4), 20, 4, sort.by.query=TRUE)
```
integer-utils

Some utility functions to operate on integer vectors

Description

Some low-level utility functions to operate on ordinary integer vectors.

Usage

isSequence(x, of.length=length(x))

toListOfIntegerVectors(x, sep=",")

## more to come...

Arguments

x
  For isSequence(): An integer vector.
  For toListOfIntegerVectors(): A character vector where each element is a
  string containing comma-separated integers in decimal representation. Alter-
  natively x can be a list of raw vectors, in which case it’s treated like if it was
  sapply(x, rawToChar).

of.length
  The expected length of the integer sequence.

sep
  The separator represented as a single-letter string.

Details

isSequence() returns TRUE or FALSE depending on whether x is identical to seq_len(of.length)
or not.
toListOfIntegerVectors() is a fast and memory-efficient implementation of

  lapply(strsplit(x, sep, fixed=TRUE), as.integer)

but, unlike the above code, it will raise an error if the input contains NAs or strings that don’t
represent integer values.
Value

A list parallel to x where each list element is an integer vector.

Author(s)

Hervé Pagès

See Also

- The seq_len function in the base package.
- The strsplit function in the base package.

Examples

```r
## ---------------------------------------------------------------------
## isSequence()
## ---------------------------------------------------------------------
isSequence(1:5) # TRUE
isSequence(5:1) # FALSE
isSequence(0:5) # FALSE
isSequence(integer(0)) # TRUE
isSequence(1:5, of.length=5) # TRUE (the expected length)
isSequence(1:5, of.length=6) # FALSE (not the expected length)

## ---------------------------------------------------------------------
## toListOfIntegerVectors()
## ---------------------------------------------------------------------
x <- c("1116,0,-19",
    " +55291 , 2476.",
    "19184,4269,5659,6470,6721,7469,14601",
    "7778889, 426900, -4833,5659,6470,6721,7096",
    "19184 , -99999")
y <- toListOfIntegerVectors(x) y

## When it doesn't choke on an NA or string that doesn't represent
## an integer value, toListOfIntegerVectors() is equivalent to
## the function below but is faster and more memory-efficient:
toListofIntegerVectors2 <- function(x, sep="",)
{
    lapply(strsplit(x, sep, fixed=TRUE), as.integer)
}
y2 <- toListofIntegerVectors2(x)
stopifnot(identical(y, y2))
```
isSorted

Test if a vector-like object is sorted

Description

isSorted and isStrictlySorted test if a vector-like object is sorted or strictly sorted, respectively.
isConstant tests if a vector-like or array-like object is constant. Currently only isConstant methods for vectors or arrays of type integer or double are implemented.

Usage

isSorted(x)

isStrictlySorted(x)

isConstant(x)

Arguments

x A vector-like object. Can also be an array-like object for isConstant.

Details

Vector-like objects of length 0 or 1 are always considered to be sorted, strictly sorted, and constant. Strictly sorted and constant objects are particular cases of sorted objects.
isStrictlySorted(x) is equivalent to isSorted(x) && !anyDuplicated(x)

Value

A single logical i.e. TRUE, FALSE or NA.

Author(s)

Hervé Pagès

See Also

- is.unsorted.
- duplicated and unique.
- all.equal.
- NA and is.finite.
Examples

```r
## A. isSorted() and isStrictlySorted()
##
x <- 1:10

isSorted(x)            # TRUE
isSorted(-x)           # FALSE
isSorted(rev(x))       # FALSE
isSorted(-rev(x))      # TRUE

isStrictlySorted(x)    # TRUE

x2 <- rep(x, each=2)

isSorted(x2)           # TRUE
isStrictlySorted(x2)   # FALSE
```

## B. "isConstant" METHOD FOR integer VECTORS

```r
## On a vector with no NAs:
stopifnot(isConstant(rep(-29L, 10000)))

## On a vector with NAs:
stopifnot(!isConstant(c(0L, NA, -29L)))
stopifnot(is.na(isConstant(c(-29L, -29L, NA))))

## On a vector of length <= 1:
stopifnot(isConstant(NA_integer_))
```

## C. "isConstant" METHOD FOR numeric VECTORS

```r
## This method does its best to handle rounding errors and special
## values NA, NaN, Inf and -Inf in a way that "makes sense".
## Below we only illustrate handling of rounding errors.

## Here values in 'x' are "conceptually" the same:
x <- c(11/3,
      2/3 + 4/3 + 5/3,
      50 + 11/3 - 50,
      7.00001 - 1000003/300000)

## However, due to machine rounding errors, they are not *strictly*
## equal:
duplicated(x)
unique(x)

## only *nearly* equal:
all.equal(x, rep(11/3, 4)) # TRUE
```
```r
## 'isConstant(x)' uses 'all.equal()' internally to decide whether
## the values in 'x' are all the same or not:
stopifnot(isConstant(x))

## This is not perfect though:
isConstant((x - 11/3) * 1e8)  # FALSE on Intel Pentium paltforms
  # (but this is highly machine dependent!)
```

---

### List-class List objects

#### Description

List objects are Vector objects with a "\[\]", elementType and elementNROWS method. The List class serves a similar role as list in base R.

It adds one slot, the elementType slot, to the two slots shared by all Vector objects.

The elementType slot is the preferred location for List subclasses to store the type of data represented in the sequence. It is designed to take a character of length 1 representing the class of the sequence elements. While the List class performs no validity checking based on elementType, if a subclass expects elements to be of a given type, that subclass is expected to perform the necessary validity checking. For example, the subclass IntegerList (defined in the IRanges package) has elementType = "integer" and its validity method checks if this condition is TRUE.

To be functional, a class that inherits from List must define at least a "\[\]" method (in addition to the minimum set of Vector methods).

#### Construction

List objects and derivatives are typically constructed using one of the following methods:

**Use of a constructor function:** Many constructor functions are provided in S4Vectors and other Bioconductor packages for List objects and derivatives e.g. List(), IntegerList(), RleList(), IntegerRangesList(), GRangesList(), etc...

Which one to use depends on the particular type of List derivative one wishes to construct e.g. use IntegerList() to get an IntegerList object, RleList() to get an RleList object, etc...

Note that the name of a constructor function is always the name of a valid class. See the man page of a particular constructor function for the details.

**Coercion to List or to a List subclass:** Many coercion methods are defined in S4Vectors and other Bioconductor packages to turn all kinds of objects into List objects.

One general and convenient way to convert any vector-like object x into a List is to call as(x, "List"). This will yield an object from a subclass of List. Note that this subclass will typically extend CompressedList but not necessarily (see ?CompressedList in the IRanges package for more information about CompressedList objects).

However, if a specific type of List derivative is desired (e.g. CompressedGRangesList), then coercing explicitly to that class is preferrable as it is more robust and more readable.
Use of `splitAsList()`, `relist()`, or `extractList()`:

- `splitAsList()` behaves like `base::split()` except that it returns a List derivative instead of an ordinary list. See ?`splitAsList` for more information.
- The `relist()` methods for List objects and derivatives, as well as the `extractList()` function, are defined in the `IRanges` package. They provide very efficient ways to construct a List derivative from the vector-like object passed to their first argument (flesh for `relist()` and `x` for `extractList()`). See ?`extractList` in the `IRanges` package for more information.

Accessors

In the following code snippets, `x` is a List object.

- `length(x)`: Get the number of list elements in `x`.
- `names(x)`, `names(x) <- value`: Get or set the names of the elements in the List.
- `mcols(x, use.names=FALSE), mcols(x) <- value`: Get or set the metadata columns. See Vector man page for more information.
- `elementType(x)`: Get the scalar string naming the class from which all elements must derive.
- `elementNROWS(x)`: Get the length (or nb of row for a matrix-like object) of each of the elements. Equivalent to `sapply(x, NROW)`.
- `isEmpty(x)`: Returns a logical indicating either if the sequence has no elements or if all its elements are empty.

Coercion

To List.

- `as(x, "List")`: Converts a vector-like object into a List, usually a `CompressedList` derivative. One notable exception is when `x` is an ordinary list, in which case `as(x, "List")` returns a `SimpleList` derivative.
- To explicitly request a `SimpleList` derivative, call `as(x, "SimpleList")`.
- See ?`CompressedList` (you might need to load the `IRanges` package first) and ?`SimpleList` for more information about the CompressedList and SimpleList representations.

From List. In the code snippets below, `x` is a List object.

- `as.list(x, ...), as(from, "list")`: Turns `x` into an ordinary list.
- `unlist(x, recursive=TRUE, use.names=TRUE)`: Concatenates the elements of `x` into a single vector-like object (of class `elementType(x)`).
- `as.data.frame(x, row.names=NULL, optional=FALSE, value.name="value", use.outer.mcols=FALSE, group_name.as.factor=FALSE, ...)`: Coerces a List to a data.frame. The result has the same length as unlisted `x` with two additional columns, `group` and `group_name`. `group` is an integer that indicates which list element the record came from. `group_name` holds the list name associated with each record; `value` is character by default and factor when `group_name.as.factor` is TRUE.
- When `use.outer.mcols` is TRUE the metadata columns on the outer list elements of `x` are replicated out and included in the `data.frame`. List objects that unlist to a single vector (column) are given the column name ‘value’ by default. A custom name can be provided in `value.name`
Splitting values in the resulting data.frame by the original groups in x should be done using the group column as the f argument to splitAsList. To relist data, use x as the skeleton argument to relist.

Subsetting

In the code snippets below, x is a List object.

x[i]: Return a new List object made of the list elements selected by subscript i. Subscript i can be of any type supported by subsetting of a Vector object (see Vector man page for the details), plus the following types: IntegerList, LogicalList, CharacterList, integer-RleList, logical-RleList, character-RleList, and IntegerRangesList. Those additional types perform subsetting within the list elements rather than across them.

x[i] <- value: Replacement version of x[i].

x[[i]]: Return the selected list element i, where i is an numeric or character vector of length 1.

x[[i]] <- value: Replacement version of x[[i]].

x$name, x$name <- value: Similar to x[[name]] and x[[name]] <- value, but name is taken literally as an element name.

Author(s)

P. Aboyoun and H. Pagès

See Also

• splitAsList for splitting a vector-like object into a List object.
• relist and extractList in the IRanges package for efficiently constructing a List derivative from a vector-like object.
• List-utils for common operations on List objects.
• Vector objects for the parent class.
• The SimpleList class for a direct extension of the List class.
• The CompressedList class defined in the IRanges package for another direct extension of the List class.
• The IntegerList, RleList, and IRanges classes and constructors defined in the IRanges package for some examples of List derivatives.

Examples

showClass("List")  # shows only the known subclasses define in this package

## A. CONSTRUCTION

x <- sample(500, 20)
y0 <- splitAsList(x, x %% 4)
y0
 levels <- paste0("G", 1:10)
f1 <- factor(sample(levels, length(x), replace=TRUE), levels=levels)
y1 <- splitAsList(x, f1)
y1

f2 <- factor(sample(levels, 26, replace=TRUE), levels=levels)
y2 <- splitAsList(letters, f2)
y2

library(IRanges) # for the NumericList() constructor and the
# coercion to CompressedCharacterList

NumericList(A=runif(10), B=NULL, C=runif(3))

## Another way to obtain 'splitAsList(letters, f2)' but using
## 'splitAsList()' should be preferred as it is a lot more efficient:
y2b <- as(split(letters, f2), "CompressedCharacterList") # inefficient!
stopifnot(identical(y2, y2b))

## B. SUBSETTING
## ---------------------------------------------------------------------
## Single-bracket and double-bracket subsetting behave like on ordinary
## lists:
y1[c(10, 1, 2, 2)]
y1[c(-10, -1, -2)]
y1[c(TRUE, FALSE)]
y1[c("G8", "G1")]
head(y1)
tail(y1, n=3)
y1[[2]] # note the difference with y1[2]
y1["G2"] # note the difference with y1["G2"]

y0[["3"]]
y0[[3]]

## In addition to all the forms of subscripting supported by ordinary
## lists, List objects and derivatives accept a subscript that is a
## list-like object. This form of subsetting is called "list-style
## subsetting":
i <- list(4:3, -2, 1) # ordinary list
y1[i]
i <- y1 >= 200 # LogicalList object
y1[i]

## List-style subsetting also works with an RleList or IntegerRangesList
## subscript:
i <- RleList(y1 >= 200) # RleList object
y1[i]
i <- IRangesList(RleList(y1 >= 200)) # IRangesList object
y1[i]

## ---------------------------------------------------------------------
# C. THE "UNLIST -> TRANSFORM -> RELIST" IDiom

The "unlist -> transform -> relist" idiom is a very efficient way to apply the same simple transformation to all the **inner elements** of a list-like object (i.e. to all the elements of its list elements). The result is another list-like object with the same shape as the original object (but not necessarily the same class):

```r
relist(sqrt(unlist(y1)), y1)
relist(toupper(unlist(y2)), y2)
```

However note that `sqrt()`, `toupper()`, and many other base functions, can be used directly on a list derivative. This is because the IRanges package defines methods for these functions that know how to handle List objects:

```r
sqrt(y1) # same as 'relist(sqrt(unlist(y1)), y1)'
toupper(y2) # same as 'relist(toupper(unlist(y2)), y2)'
```

---

**List-utils**

Common operations on List objects

**Description**

Various functions and methods for looping on List objects, functional programming on List objects, and evaluation of an expression in a List object.

**Usage**

```
# Looping on List objects:
# ------------------------

# S4 method for signature 'List'
lapply(X, FUN, ...)

# S4 method for signature 'List'
sapply(X, FUN, ..., simplify=TRUE, USE.NAMES=TRUE)

endoapply(X, FUN, ...)

revElements(x, i)

mendoapply(FUN, ..., MoreArgs=NULL)

c(...)

# Functional programming methods for List objects:
# -----------------------------------------------

# S4 method for signature 'List'
```
Reduce(f, x, init, right=FALSE, accumulate=FALSE)
## S4 method for signature 'List'
Filter(f, x)
## S4 method for signature 'List'
Find(f, x, right=FALSE, nomatch=NULL)
## S4 method for signature 'List'
Map(f, ...)
## S4 method for signature 'List'
Position(f, x, right=FALSE, nomatch=NA_integer_)

## Evaluation of an expression in a List object:
## ---------------------------------------------
within(data, expr, ...)

## Constructing list matrices:
## ---------------------------------------------
rbind(..., deparse.level=1L)
## S4 method for signature 'List'
cbind(..., deparse.level=1L)

Arguments

X, x
A list, data.frame or List object.

FUN
The function to be applied to each element of X (for endoapply) or for the elements in ... (for mendoapply).

... For lapply, sapply, and endoapply, optional arguments to FUN.
For mendoapply, pc and Map, one or more list-like objects.

simplify, USE.NAMES
See ?base::sapply for a description of these arguments.

MoreArgs A list of other arguments to FUN.

i
Index specifying the elements to replace. Can be anything supported by `[<-'.

f, init, right, accumulate, nomatch
See ?base::Reduce for a description of these arguments.

data A List object.

expr Expression to evaluate.

deparse.level See ?base::rbind for a description of this argument.

Details

Looping on List objects: Like the standard lapply function defined in the base package, the lapply method for List objects returns a list of the same length as X, with each element being the result of applying FUN to the corresponding element of X.
Like the standard `sapply` function defined in the `base` package, the `sapply` method for `List` objects is a user-friendly version of `lapply` by default returning a vector or matrix if appropriate.

`endoapply` and `mendoapply` perform the endomorphic equivalents of `lapply` and `mapply` by returning objects of the same class as the inputs rather than an ordinary list.

`revElements(x, i)` reverses the list elements in `x` specified by `i`. It's equivalent to, but faster than, doing `x[i] <- endoapply(x[i], rev)`.

`pc(...)` combine list-like objects by concatenating them in an element-wise fashion. It's similar to, but faster than, `mapply(c, ..., SIMPLIFY=FALSE)`. With the following differences:

1. `pc()` ignores the supplied objects that are NULL.
2. `pc()` does not recycle its arguments. All the supplied objects must have the same length.
3. If one of the supplied objects is a `List` object, then `pc()` returns a `List` object.
4. `pc()` always returns a homogenous list or `List` object, that is, an object where all the list elements have the same type.

**Functional programming methods for List objects:** The R base package defines some higher-order functions that are commonly found in Functional Programming Languages. See `?base::Reduce` for the details, and, in particular, for a description of their arguments. The `S4Vectors` package provides methods for `List` objects, so, in addition to be an ordinary vector or list, the `x` argument can also be a `List` object.

**Evaluation of an expression in a List object:** `within` evaluates `expr` within `as.env(data)` via `eval(data)`. Similar to `with`, except assignments made during evaluation are taken as assignments into `data`, i.e., new symbols have their value appended to `data`, and assigning new values to existing symbols results in replacement.

**Binding Lists into a matrix:** There are methods for `cbind` and `rbind` that will bind multiple lists together into a basic list matrix. The usual geometric constraints apply. In the future, this might return a `List (+ dimensions)`, but for now the return value is an ordinary list.

**Value**

`endoapply` returns an object of the same class as `X`, each element of which is the result of applying `FUN` to the corresponding element of `X`.

`mendoapply` returns an object of the same class as the first object specified in `...`, each element of which is the result of applying `FUN` to the corresponding elements of `...`.

`pc` returns a list or `List` object of the same length as the input objects.

See `?base::Reduce` for the value returned by the functional programming methods.

See `?base::within` for the value returned by `within`.

`cbind` and `rbind` return a list matrix.

Examples

```r
a <- data.frame(x = 1:10, y = rnorm(10))
b <- data.frame(x = 1:10, y = rnorm(10))
endoapply(a, function(x) (x - mean(x))/sd(x))
mendoapply(function(e1, e2) (e1 - mean(e1)) * (e2 - mean(e2)), a, b)

x <- list(a=11:13, b=26:21, c=letters)
y <- list(-5:1, c("foo", "bar"), 0.25)
pc(x, y)

library(IRanges)
x <- IntegerList(a=11:13, b=26:21, c=31:36, d=4:2)
y <- NumericList(-(5:1), 1:2, numeric(0), 0.25)
pc(x, y)

Reduce("+", x)

Filter(is.unsorted, x)

pos1 <- Position(is.unsorted, x)
stopifnot(identical(Find(is.unsorted, x), x[[pos1]]))

pos2 <- Position(is.unsorted, x, right=TRUE)
stopifnot(identical(Find(is.unsorted, x, right=TRUE), x[[pos2]]))

y <- x * 1000L
Map("c", x, y)

rbind(x, y)
cbind(x, y)
```

---

### LLint-class

#### LLint vectors

**Description**

The LLint class is a container for storing a vector of large integers (i.e. long long int values at the C level).
Usage

LLint(length=0L)
as.LLint(x)
is.LLint(x)

Arguments

length A non-negative number (i.e. integer, double, or LLint value) specifying the
desired length.

x Object to be coerced or tested.

Details

LLint vectors aim to provide the same functionality as integer vectors in base R but their values
are stored as long long int values at the C level vs int values for integer vectors. Note that on Intel
platforms long long int values are 64-bit and int values 32-bit only. Therefore LLint vectors can
hold values in the +/-9.223e18 range (approximately) vs +/-2.147e9 only for integer vectors.
NAs are supported and the NA_LLInt_ constant is predefined for convenience as as(NA, "LLint").
Names are not supported for now.
Coercions from/to logical, integer, double, and character are supported.
Operations from the Arith, Compare and Summary groups are supported.
More operations coming soon...

as.LLint(3e9)
as.LLint("3000000000")

x <- as.LLint(1:10 * 11111111)
x * x  # result as vector of doubles (i.e. 'x' coerced to double)
5 * x  # result as LLint vector (i.e. 5L coerced to LLint vector)
max(x)
min(x)
range(x)
sum(x)

x <- as.LLint(1:20)
prod(x)
prod(x)  # result is out of LLint range (+/-9.223e18)
prod(as.numeric(x))

x <- as.LLint(1:20)
sum(x * x * x) == sum(x) * sum(x)

## Note that max(), min() and range() *always* return an LLint vector
## when called on an LLint vector, even when the vector is empty:
max(LLint()) # NA with no warning
min(LLint()) # NA with no warning

## This differs from how max(), min() and range() behave on an empty
## integer vector:
max(integer()) # -Inf with a warning
min(integer()) # Inf with a warning

## ---------------------------------------------------------------------
## GOING FROM STRINGS TO INTEGERS
## ---------------------------------------------------------------------

## as.integer() behaves like as.integer(as.double()) on a character
## vector. With the following consequence:
s <- "-2.9999999999999999"
as.integer(s)  # -3

## as.LLint() converts the string *directly* to LLint, without
## coercing to double first:
as.LLint(s)  # decimal part ignored

## ---------------------------------------------------------------------
## GOING FROM DOUBLE-PRECISION VALUES TO INTEGERS AND VICE-VERSA
## ---------------------------------------------------------------------

## Be aware that a double-precision value is not guaranteed to represent
## exactly an integer > 2^53. This can cause some surprises:
2^53 == 2^53 + 1  # TRUE, yep!

## And therefore:
as.LLint(2^53) == as.LLint(2^53 + 1)  # also TRUE

## This can be even more disturbing when passing a big literal integer
## value because the R parser will turn it into a double-precision value
## before passing it to as.LLint():

```r
x1 <- as.LLint(9007199254740992)  # same as as.LLint(2^53)
x1
x2 <- as.LLint(9007199254740993)  # same as as.LLint(2^53 + 1)
x2
x1 == x2  # still TRUE
```

## However, no precision is lost if a string literal is used instead:

```r
x1 <- as.LLint("9007199254740992")
x1
x2 <- as.LLint("9007199254740993")
x2
x1 == x2  # FALSE
```

```r
d1 <- as.double(x1)
d2 <- as.double(x2)  # warning!
d1 == d2  # TRUE
```

## LLint IS IMPLEMENTED AS AN S4 CLASS

```r
class(LLint(10))
typeof(LLint(10))  # S4
storage.mode(LLint(10))  # S4
is.vector(LLint(10))  # FALSE
is.atomic(LLint(10))  # FALSE
```

This means that an LLint vector cannot go in an ordinary data frame:

```r
## Not run:
data.frame(id=as.LLint(1:5))  # error!
## End(Not run)
```

## SANITY CHECKS

```r
x <- as.integer(c(0, 1, -1, -3, NA, -99))
y <- as.integer(c(-6, NA, -4:3, 0, 1999, 6:10, NA))
xx <- as.LLint(x)
yy <- as.LLint(y)

## Operations from "Arith" group:
stopifnot(identical(x + y, as.integer(xx + yy)))
stopifnot(identical(as.LLint(y + x), yy + xx))
stopifnot(identical(x - y, as.integer(xx - yy)))
stopifnot(identical(as.LLint(y - x), yy - xx))
stopifnot(identical(x * y, as.integer(xx * yy)))
```
Pairs-class

## Operations from "Compare" group:

```r
stopifnot(identical(x == y, xx == yy))
stopifnot(identical(y == x, yy == xx))
stopifnot(identical(x != y, xx != yy))
stopifnot(identical(y != x, yy != xx))
stopifnot(identical(x <= y, xx <= yy))
stopifnot(identical(y <= x, yy <= xx))
stopifnot(identical(x >= y, xx >= yy))
stopifnot(identical(y >= x, yy >= xx))
```

## Operations from "Summary" group:

```r
stopifnot(identical(max(y), as.integer(max(yy))))
stopifnot(identical(max(y, na.rm=TRUE), as.integer(max(yy, na.rm=TRUE))))
stopifnot(identical(min(y), as.integer(min(yy))))
stopifnot(identical(min(y, na.rm=TRUE), as.integer(min(yy, na.rm=TRUE))))
stopifnot(identical(range(y), as.integer(range(yy))))
stopifnot(identical(range(y, na.rm=TRUE), as.integer(range(yy, na.rm=TRUE))))
stopifnot(identical(sum(y), as.integer(sum(yy))))
stopifnot(identical(sum(y, na.rm=TRUE), as.integer(sum(yy, na.rm=TRUE))))
stopifnot(identical(prod(y), as.double(prod(yy))))
stopifnot(identical(prod(y, na.rm=TRUE), as.double(prod(yy, na.rm=TRUE))))
```

---

**Pairs-class**  
*Pairs objects*

---

**Description**

*Pairs* is a Vector that stores two parallel vectors (any object that can be a column in a DataFrame). It provides conveniences for performing binary operations on the vectors, as well as for converting between an equivalent list representation. Virtually all of the typical R vector operations should behave as expected.

A typical use case is representing the pairing from a `findOverlaps` call, for which `findOverlapPairs` is a shortcut.
**Pairs-class**

**Constructor**

Pairs(first, second, ..., names = NULL, hits = NULL): Constructs a Pairs object by aligning the vectors first and second. The vectors must have the same length, unless hits is specified. Arguments in ... are combined as columns in the mcols of the result. The names argument specifies the names on the result. If hits is not NULL, it should be a Hits object that collates the elements in first and second to produce the corresponding pairs.

**Accessors**

In the code snippets below, x is a Pairs object.

names(x), names(x) <- value: get or set the names

first(x), first(x) <- value: get or set the first member of each pair

second(x), second(x) <- value: get or set the second member of each pair

**Coercion**

zipup(x): Interleaves the Pairs object x into a list, where each element is composed of a pair. The type of list depends on the type of the elements.

zipdown(x): The inverse of zipup(). Converts x, a list where every element is of length 2, to a Pairs object, by assuming that each element of the list represents a pair.

**Subsetting**

In the code snippets below, x is a Pairs object.

x[i]: Subset the Pairs object.

**Author(s)**

Michael Lawrence

**See Also**

- Hits-class, a typical way to define a pairing.
- findOverlapPairs in the IRanges package, which generates an instance of this class based on overlaps.
- setops-methods in the IRanges package, for set operations on Pairs objects.

**Examples**

```r
p <- Pairs(1:10, Rle(1L, 10), score=rnorm(10), names=letters[1:10])
identical(first(p), 1:10)
mcols(p)$score
p
as.data.frame(p)
z <- zipup(p)
first(p) <- Rle(1:10)
identical(zipdown(z), p)
```
Description

RectangularData is a virtual class with no slots to be extended by classes that aim at representing objects with a 2D rectangular shape.

Some examples of RectangularData extensions are:

- The DataFrame class defined in this package (S4Vectors).
- The DelayedMatrix class defined in the DelayedArray package.
- The SummarizedExperiment and Assays classes defined in the SummarizedExperiment package.

Details

Any object that belongs to a class that extends RectangularData is called a RectangularData derivative.

Users should be able to access and manipulate RectangularData derivatives via the standard 2D API defined in base R, that is, using things like `dim()`, `nrow()`, `ncol()`, `dimnames()`, the 2D form of `[ (x[i, j]), rbind(), cbind(), etc...

Not all RectangularData derivatives will necessarily support the full 2D API but they must support at least `dim()`, `nrow(x)`, `ncol(x)`, `NROW(x)`, and `NCOL(x)`. And of course, `dim()` must return an integer vector of length 2 on any of these objects.

Developers who implement RectangularData extensions should also make sure that they support low-level operations `bindROWS()` and `bindCOLS()`.

Accessors

In the following code snippets, `x` is a RectangularData derivative. Not all RectangularData derivatives will support all these accessors.

`dim(x)`: Length two integer vector defined as `c(nrow(x), ncol(x))`. Must work on any RectangularData derivative.

`nrow(x), ncol(x)`: Get the number of rows and columns, respectively. Must work on any RectangularData derivative.

`NROW(x), NCOL(x)`: Same as `nrow(x)` and `ncol(x)`, respectively. Must work on any RectangularData derivative.

`dimnames(x)`: Length two list of character vectors defined as `list(rownames(x), colnames(x))`.

`rownames(x), colnames(x)`: Get the names of the rows and columns, respectively.
Subsetting

In the code snippets below, x is a RectangularData derivative.

\[
x[i, j, \text{drop=}\text{TRUE}]
\]

Return a new RectangularData derivative of the same class as x made of the
selected rows and columns.

For single row and/or column selection, the drop argument specifies whether or not to "drop
the dimensions" of the result. More precisely, when \(\text{drop=}\text{TRUE}\) (the default), a single row or
column is returned as a vector-like object (of length/NROW equal to ncol(x) if a single row,
or equal to nrow(x) if a single column).

Not all RectangularData derivatives support the drop argument. For example DataFrame and
DelayedMatrix objects support it (only for a single column selection for DataFrame objects),
but SummarizedExperiment objects don’t (drop is ignored for these objects and subsetting
always returns a SummarizedExperiment derivative of the same class as x).

\[
\text{head}(x, n=6L)
\]

If \(n\) is non-negative, returns the first \(n\) rows of the RectangularData derivative. If
\(n\) is negative, returns all but the last abs(\(n\)) rows of the RectangularData derivative.

\[
\text{tail}(x, n=6L)
\]

If \(n\) is non-negative, returns the last \(n\) rows of the RectangularData derivative. If
\(n\) is negative, returns all but the first abs(\(n\)) rows of the RectangularData derivative.

\[
\text{subset}(x, \text{subset}, \text{select}, \text{drop=}\text{FALSE})
\]

Return a new RectangularData derivative using:

- \text{subset} logical expression indicating rows to keep, where missing values are taken as FALSE.
- \text{select} expression indicating columns to keep.
- \text{drop} passed on to \([\) indexing operator.

Combining

In the code snippets below, all the input objects are expected to be RectangularData derivatives.

\[
\text{rbind}(\ldots)
\]

Creates a new RectangularData derivative by aggregating the rows of the input objects.

\[
\text{cbind}(\ldots)
\]

Creates a new RectangularData derivative by aggregating the columns of the input objects.

\[
\text{combineRows}(x, \ldots)
\]

Creates a new RectangularData derivative (of the same class as \(x\)) by aggregating
the rows of the input objects. Unlike rbind(), combineRows() will handle cases
involving differences in the column names of the input objects by adding the missing columns
to them, and filling these columns with NAs. The column names of the returned object are a
union of the column names of the input objects.

Behaves like an \textit{endomorphism} with respect to its first argument i.e. returns an object of the
same class as \(x\).

Finally note that this is a generic function with methods defined for DataFrame objects and
other RectangularData derivatives.

\[
\text{combineCols}(x, \ldots, \text{use.names=}\text{TRUE})
\]

Creates a new RectangularData derivative (of the same class as \(x\)) by aggregating the columns of the input objects. Unlike cbind(), combineCols() will handle cases
involving differences in the number of rows of the input objects.

If \text{use.names=}\text{TRUE}, all objects are expected to have non-NULL, non-duplicated row names.
These row names do not have to be the same, or even shared, across the input objects. Missing
rows in any individual input object are filled with NAs, such that the row names of the returned
object are a union of the row names of the input objects.
If use.names=FALSE, all objects are expected to have the same number of rows, and this function behaves the same as cbind(). The row names of the returned object is set to rownames(x). Differences in the row names between input objects are ignored.

Behaves like an endomorphism with respect to its first argument i.e. returns an object of the same class as x.

Finally note that this is a generic function with methods defined for DataFrame objects and other RectangularData derivatives.

combineUniqueCols(x, ..., use.names=TRUE): Same as combineCols(), but this function will attempt to collapse multiple columns with the same name across the input objects into a single column in the output. This guarantees that the column names in the output object are always unique. The only exception is for unnamed columns, which are not collapsed. The function works on any rectangular objects for which combineCols() works.

When use.names=TRUE, collapsing is only performed if the duplicated column has identical values for the shared rows in the input objects involved. Otherwise, the contents of the later input object is simply ignored with a warning. Similarly, if use.names=FALSE, the duplicated columns must be identical for all rows in the affected input objects.

Behaves like an endomorphism with respect to its first argument i.e. returns an object of the same class as x.

Finally note that this function is implemented on top of combineCols() and is expected to work on any RectangularData derivatives for which combineCols() works.

---

**Rle-class**

**Rle objects**

**Description**

The Rle class is a general container for storing an atomic vector that is stored in a run-length encoding format. It is based on the rle function from the base package.
Constructor

Rle(values, lengths): This constructor creates an Rle instance out of an atomic vector or factor object values and an integer or numeric vector lengths with all positive elements that represent how many times each value is repeated. The length of these two vectors must be the same. lengths can be missing in which case values is turned into an Rle.

Getters

In the code snippets below, x is an Rle object:

runLength(x): Returns the run lengths for x.
runValue(x): Returns the run values for x.
nrun(x): Returns the number of runs in x.
start(x): Returns the starts of the runs for x.
end(x): Returns the ends of the runs for x.
width(x): Same as runLength(x).

Setters

In the code snippets below, x is an Rle object:

runLength(x) <- value: Replaces x with a new Rle object using run values runValue(x) and run lengths value.
runValue(x) <- value: Replaces x with a new Rle object using run values value and run lengths runLength(x).

Coercion

From atomic vector to Rle: In the code snippets below, from is an atomic vector:
as(from, "Rle") : This coercion creates an Rle instances out of an atomic vector from.

From Rle to other objects: In the code snippets below, x and from are Rle objects:
as.vector(x, mode="any"), as(from, "vector") : Creates an atomic vector based on the values contained in x. The vector will be coerced to the requested mode, unless mode is "any", in which case the most appropriate type is chosen.
as.factor(x), as(from, "factor") : Creates a factor object based on the values contained in x.
as.data.frame(x, as(from, "data.frame") : Creates a data.frame with a single column holding the result of as.vector(x).
decode(x) : Converts an Rle to its native form, such as an atomic vector or factor. Calling decode on a non-Rle will return x by default, so it is generally safe for ensuring that an object is native.
General Methods

In the code snippets below, \(x\) is an Rle object:

\[
x[i, \text{drop=getOption("dropRle", default=FALSE))]: \text{Subsets } x \text{ by index } i, \text{ where } i \text{ can be positive integers, negative integers, a logical vector of the same length as } x, \text{ an Rle object of the same length as } x \text{ containing logical values, or an IRanges object. When drop=} \text{TRUE, returns an atomic vector.}
\]

\[
x[i] <- \text{value}: \text{Replaces elements in } x \text{ specified by } i \text{ with corresponding elements in value. Supports the same types for } i \text{ as } x[i].
\]

\[
x \%in\% \text{table: Returns a logical Rle representing set membership in table.}
\]

\[
c(x, \ldots, \text{ignore.mcols=}\text{FALSE}): \text{Concatenate Rle object } x \text{ and the Rle objects in } \ldots \text{ together. See } \text{?c in this package (the S4Vectors package) for more information about concatenating Vector derivatives.}
\]

\[
\text{append}(x, \text{values, after} = \text{length}(x)): \text{Insert one Rle into another Rle.}
\]

\[
\text{match}(x, \text{table, nomatch=} \text{NA_integer}, \text{incomparables=} \text{NULL}): \text{Matches the values in } x \text{ to table:}
\]

\[
\text{rev}(x): \text{Reverses the order of the values in } x.
\]

\[
\text{show(object): Prints out the Rle object in a user-friendly way.}
\]
order(..., na.last=TRUE, decreasing=FALSE, method=c("auto", "shell", "radix")): Returns a permutation which rearranges its first argument into ascending or descending order, breaking ties by further arguments. See order.
sort(x, decreasing=FALSE, na.last=NA): Sorts the values in x.
  decreasing If TRUE, sorts values in decreasing order. If FALSE, sorts values in increasing order.
  na.last If TRUE, missing values are placed last. If FALSE, they are placed first. If NA, they are removed.
subset(x, subset): Returns a new Rle object made of the subset using logical vector subset.
table(...): Returns a table containing the counts of the unique values. Supported arguments include useNA with values of ‘no’ and ‘ifany’. Multiple Rle's must be concatenated with c() before calling table.
tabulate(bin, nbins = max(bin, 1L, na.rm = TRUE)): Just like tabulate, except optimized for Rle.
tail(x, n = 6L): If n is non-negative, returns the last n elements of x. If n is negative, returns all but the first abs(n) elements of x.
unique(x, incomparables = FALSE, ...): Returns the unique run values. The incomparables argument takes a vector of values that cannot be compared with FALSE being a special value that means that all values can be compared.

Set Operations
In the code snippets below, x and y are Rle object or some other vector-like object:
setdiff(x, y): Returns the unique elements in x that are not in y.
union(x, y): Returns the unique elements in either x or y.
intersect(x, y): Returns the unique elements in both x and y.

Rle-runstat  

**Fixed-width running window summaries**

### Description

The `runsum`, `runmean`, `runmed`, `runwtsum`, `runq` functions calculate the sum, mean, median, weighted sum, and order statistic for fixed width running windows.

### Usage

```r
runsum(x, k, endrule = c("drop", "constant"), ...)
runmean(x, k, endrule = c("drop", "constant"), ...)

## S4 method for signature 'Rle'
smoothEnds(y, k = 3)

## S4 method for signature 'Rle'
runmed(x, k, endrule = c("median", "keep", "drop", "constant"),
       algorithm = NULL, print.level = 0)
runwtsum(x, k, wt, endrule = c("drop", "constant"), ...)
runq(x, k, i, endrule = c("drop", "constant"), ...)
```

### Arguments

- `x, y`  
The data object.
- `k`  
An integer indicating the fixed width of the running window. Must be odd when `endrule != "drop"`.
- `endrule`  
A character string indicating how the values at the beginning and the end (of the data) should be treated.

"median" see `runmed`;
"keep" see runmed;
drop" do not extend the running statistics to be the same length as the under-
lying vectors;
"constant" copies running statistic to the first values and analogously for the
last ones making the smoothed ends constant.

wt A numeric vector of length k that provides the weights to use.
i An integer in [0, k] indicating which order statistic to calculate.
algorithm, print.level
See ?stats::runmed for a description of these arguments.
...
Additional arguments passed to methods. Specifically, na.rm. When na.rm =
TRUE, the NA and NaN values are removed. When na.rm = FALSE, NA is returned
if either NA or NaN are in the specified window.

Details
The runsum, runmean, runmed, runwtsum, and runq functions provide efficient methods for calcu-
lating the specified numeric summary by performing the looping in compiled code.

Value
An object of the same class as x.

runsum(x, k = 3, endrule = "constant")
runmean(x, k = 3)
runwtsum(x, k = 3, wt = c(0.25, 0.5, 0.25))
runq(x, k = 5, i = 3, endrule = "constant")

## Missing and non-finite values
x <- Rle(c(1, 2, NA, 0, 3, Inf, 4, NaN))
runsum(x, k = 2)
runsum(x, k = 2, na.rm = TRUE)
runmean(x, k = 2, na.rm = TRUE)
runwtsum(x, k = 2, wt = c(0.25, 0.5), na.rm = TRUE)
runq(x, k = 2, i = 2, na.rm = TRUE) ## max value in window

## The .naive_runsum() function demonstrates the semantics of
## runsum(.). This test ensures the behavior is consistent with
## base::sum().
.naive_runsum <- function(x, k, na.rm=FALSE)
  sapply(0:(length(x)-k),
      function(offset) sum(x[1:k + offset], na.rm=na.rm))

x0 <- c(1, Inf, 3, 4, 5, NA)
x <- Rle(x0)
target1 <- .naive_runsum(x0, 3, na.rm = TRUE)
target2 <- .naive_runsum(x, 3, na.rm = TRUE)
stopifnot(target1 == target2)
current <- as.vector(runsum(x, 3, na.rm = TRUE))
stopifnot(target1 == current)

## runmean() and runwtsum() :
  x <- Rle(c(2, 1, NA, 0, 1, -Inf))
  runmean(x, k = 3)
  runmean(x, k = 3, na.rm = TRUE)
  runwtsum(x, k = 3, wt = c(0.25, 0.50, 0.25))
  runwtsum(x, k = 3, wt = c(0.25, 0.50, 0.25), na.rm = TRUE)

## runq() :
  runq(x, k = 3, i = 1, na.rm = TRUE) ## smallest value in window
  runq(x, k = 3, i = 3, na.rm = TRUE) ## largest value in window

## When na.rm = TRUE, it is possible the number of non-NA
## values in the window will be less than the 'i' specified.
## Here we request the 4th smallest value in the window,
## which translates to the value at the 4/5 (0.8) percentile.
x <- Rle(c(1, 2, 3, 4, 5))
  runq(x, k=length(x), i=4, na.rm=TRUE)

## The same request on a Rle with two missing values
## finds the value at the 0.8 percentile of the vector
## at the new length of 3 after the NA's have been removed.
## This translates to round((0.8) * 3).
x <- Rle(c(1, 2, 3, NA, NA))
  runq(x, k=length(x), i=4, na.rm=TRUE)

Rle-utils

Description

Common operations on Rle objects.

Group Generics

Rle objects have support for S4 group generic functionality:

Arith "+", ",", ",", ",&", "/"
Rle-utils

Compare "==", ">", "<", "!=", "<=", ">=")
Logic "&", "|
Ops "Arith", "Compare", "Logic"
Math2 "round", "signif"
Summary "max", "min", "range", "prod", "sum", "any", "all"
Complex "Arg", "Conj", "Im", "Mod", "Re"

See S4groupGeneric for more details.

Summary

In the code snippets below, x is an Rle object:

summary(object, ..., digits = max(3, getOption("digits") - 3)): Summarizes the Rle object using an atomic vector convention. The digits argument is used for number formatting with signif().

Logical Data Methods

In the code snippets below, x is an Rle object:

!x: Returns logical negation (NOT) of x.
which(x): Returns an integer vector representing the TRUE indices of x.

Numerical Data Methods

In the code snippets below, x is an Rle object:

diff(x, lag = 1, differences = 1): Returns suitably lagged and iterated differences of x.
    lag: An integer indicating which lag to use.
    differences: An integer indicating the order of the difference.
pmax(..., na.rm = FALSE), pmax.int(..., na.rm = FALSE): Parallel maxima of the Rle input values. Removes NAs when na.rm = TRUE.
pmin(..., na.rm = FALSE), pmin.int(..., na.rm = FALSE): Parallel minima of the Rle input values. Removes NAs when na.rm = TRUE.
which.max(x): Returns the index of the first element matching the maximum value of x.
mean(x, na.rm = FALSE): Calculates the mean of x. Removes NAs when na.rm = TRUE.
var(x, y = NULL, na.rm = FALSE): Calculates the variance of x or covariance of x and y if both are supplied. Removes NAs when na.rm = TRUE.
cov(x, y, use = "everything"), cor(x, y, use = "everything"): Calculates the covariance and correlation respectively of Rle objects x and y. The use argument is an optional character string giving a method for computing covariances in the presence of missing values. This must be (an abbreviation of) one of the strings "everything", "all.obs", "complete.obs", "na.or.complete", or "pairwise.complete.obs".

sd(x, na.rm = FALSE): Calculates the standard deviation of x. Removes NA s when na.rm = TRUE.

median(x, na.rm = FALSE): Calculates the median of x. Removes NA s when na.rm = TRUE.

quantile(x, probs = seq(0, 1, 0.25), na.rm = FALSE, names = TRUE, type = 7, ...): Calculates the specified quantiles of x.

probs A numeric vector of probabilities with values in [0,1].
na.rm If TRUE, removes NA s from x before the quantiles are computed.
names If TRUE, the result has names describing the quantiles.
type An integer between 1 and 9 selecting one of the nine quantile algorithms detailed in quantile.

... Further arguments passed to or from other methods.

mad(x, center = median(x), constant = 1.4826, na.rm = FALSE, low = FALSE, high = FALSE): Calculates the median absolute deviation of x.

center The center to calculate the deviation from.
constant The scale factor.
na.rm If TRUE, removes NA s from x before the mad is computed.
low If TRUE, compute the 'lo-median'.
high If TRUE, compute the 'hi-median'.

IQR(x, na.rm = FALSE): Calculates the interquartile range of x.

na.rm If TRUE, removes NA s from x before the IQR is computed.

smoothEnds(y, k = 3): Smooth end points of an Rle y using subsequently smaller medians and Tukey’s end point rule at the very end.
k An integer indicating the width of largest median window; must be odd.

Character Data Methods

In the code snippets below, x is an Rle object:

nchar(x, type = "chars", allowNA = FALSE): Returns an integer Rle representing the number of characters in the corresponding values of x.
type One of c("bytes", "chars", "width").
allowNA Should NA be returned for invalid multibyte strings rather than throwing an error?
substr(x, start, stop), substring(text, first, last = 1000000L): Returns a character or factor Rle containing the specified substrings beginning at start/first and ending at stop/last.
chartr(old, new, x): Returns a character or factor Rle containing a translated version of x.
old A character string specifying the characters to be translated.
new A character string specifying the translations.
tolower(x): Returns a character or factor Rle containing a lower case version of x.
toupper(x): Returns a character or factor Rle containing an upper case version of x.

sub(pattern, replacement, x, ignore.case = FALSE, perl = FALSE, fixed = FALSE, useBytes = FALSE): Returns a character or factor Rle containing replacements based on matches determined by regular expression matching. See sub for a description of the arguments.

gsub(pattern, replacement, x, ignore.case = FALSE, perl = FALSE, fixed = FALSE, useBytes = FALSE): Returns a character or factor Rle containing replacements based on matches determined by regular expression matching. See gsub for a description of the arguments.

paste(..., sep = " ", collapse = NULL): Returns a character or factor Rle containing a concatenation of the values in . . .

Factor Data Methods

In the code snippets below, x is an Rle object:

levels(x), levels(x) <- value: Gets and sets the factor levels, respectively.
nlevels(x): Returns the number of factor levels.
droplevels(x): Drops unused factor levels.

sum(x)
mean(x)

z <- c("the", "quick", "red", "fox", "jumps", "over", "the", "lazy", "brown", "dog")
z <- Rle(z, seq_len(length(z)))
chartr("a", "@", z)
toupper(z)
shiftApply-methods

**Description**
Objects, classes and methods defined in the **S4Vectors** package that are not intended to be used directly.

**shiftApply-methods**
*Apply a function over subsequences of 2 vector-like objects*

**Description**
shiftApply loops and applies a function over subsequences of vector-like objects X and Y.

**Usage**

```r
shiftApply(SHIFT, X, Y, FUN, ..., OFFSET=0L, simplify=TRUE, verbose=FALSE)
```

**Arguments**

- `SHIFT`: A non-negative integer vector of shift values.
- `X, Y`: The vector-like objects to shift.
- `FUN`: The function, found via `match.fun`, to be applied to each set of shifted vectors.
- `...`: Further arguments for `FUN`.
- `OFFSET`: A non-negative integer offset to maintain throughout the shift operations.
- `simplify`: A logical value specifying whether or not the result should be simplified to a vector or matrix if possible.
- `verbose`: A logical value specifying whether or not to print the i indices to track the iterations.

**Details**
Let i be the indices in SHIFT, \( X_i = \text{window}(X, 1 + \text{OFFSET}, \text{length}(X) - \text{SHIFT}[i]) \), and \( Y_i = \text{window}(Y, 1 + \text{SHIFT}[i], \text{length}(Y) - \text{OFFSET}) \). shiftApply calculates the set of \( \text{FUN}(X_i, Y_i, \ldots) \) values and returns the results in a convenient form.

**See Also**
- The `window` and `aggregate` methods for vector-like objects defined in the **S4Vectors** package.
- `Vector` and `Rle` objects.
Examples

```r
set.seed(0)
lambda <- c(rep(0.001, 4500), seq(0.001, 10, length = 500),
            seq(10, 0.001, length = 500))
xRle <- Rle(rpois(1e7, lambda))
yRle <- Rle(rpois(1e7, lambda[251:length(lambda), 1:250]))
cor(xRle, yRle)
shifts <- seq(235, 265, by=3)
corrs <- shiftApply(shifts, yRle, xRle, FUN=cor)
cor(xRle, yRle)
shiftApply(249:251, yRle, xRle,
           FUN=function(x, y) var(x, y) / (sd(x) * sd(y)))
```

Description

Low-level utilities that control display of vector-like objects.

Usage

```r
get_showHeadLines()
set_showHeadLines(n=5)
get_showTailLines()
set_showTailLines(n=5)
```

Arguments

- `n` A non-negative integer that controls the number of vector elements to display.

Details

For the sake of keeping display compact, the `show()` methods for `Vector` derivatives only display 5 head and 5 tail vector elements.

However, the number of head and tail elements to display can be changed by setting global options `showHeadLines` and `showTailLines` to the desired values.

`get_showHeadLines()`, `set_showHeadLines()`, `get_showTailLines()`, and `set_showTailLines()` are convenience functions for getting/setting these global options.

Value

`get_showHeadLines()` and `get_showTailLines()` return the current `showHeadLines` and `showTailLines` values.

`set_showHeadLines()` and `set_showTailLines()` return the `showHeadLines` and `showTailLines` values before the change, invisibly.
**SimpleList-class**

**See Also**
- `options` in base R.
- `Vector` objects.

**Examples**
```r
library(IRanges)
ir <- IRanges(start=11:45, width=10)
ir  # displays 5 head and 5 tail ranges

set_showHeadLines(18)
ir  # displays 18 head ranges

set_showHeadLines()  # back to default
```

---

**Description**

The (non-virtual) SimpleList class extends the `List` virtual class.

**Details**

The SimpleList class is the simplest, most generic concrete implementation of the `List` abstraction. It provides an implementation that subclasses can easily extend.

In a SimpleList object the list elements are stored internally in an ordinary list.

**Constructor**

See the `List` man page for a quick overview of how to construct `List` objects in general.

The following constructor is provided for SimpleList objects:

`SimpleList(...)`: Takes possibly named objects as elements for the new SimpleList object.

**Accessors**

Same as for `List` objects. See the `List` man page for more information.

**Coercion**

All the coercions documented in the `List` man page apply to SimpleList objects.

**Subsetting**

Same as for `List` objects. See the `List` man page for more information.
**Looping and functional programming**

Same as for List objects. See `?List-utils` for more information.

**Displaying**

When a SimpleList object is displayed, the "Simple" prefix is removed from the real class name of the object. See `classNameForDisplay` for more information about this.

**See Also**

- List objects for the parent class.
- The CompressedList class defined in the IRanges package for a more efficient alternative to SimpleList.
- The SimpleIntegerList class defined in the IRanges package for a SimpleList subclass example.
- The DataFrame class for another SimpleList subclass example.

**Examples**

```r
## Displaying a SimpleList object:
x1 <- SimpleList(a=letters, i=Rle(22:20, 4:2))
class(x1)

## The "Simple" prefix is removed from the real class name of the
## object:
x1

library(IRanges)
x2 <- IntegerList(11:12, integer(0), 3:-2, compress=FALSE)
class(x2)

## The "Simple" prefix is removed from the real class name of the
## object:
x2

## This is controlled by internal helper classNameForDisplay():
classNameForDisplay(x2)
```

---

**splitAsList**

*Divide a vector-like object into groups*

**Description**

`split` divides the data in a vector-like object `x` into the groups defined by `f`.

NOTE: This man page is for the `split` methods defined in the S4Vectors package. See `?base::split` for the default method (defined in the base package).
Usage

```r
## S4 method for signature 'Vector,ANY'
split(x, f, drop=FALSE, ...)

## S4 method for signature 'ANY,Vector'
split(x, f, drop=FALSE, ...)

## S4 method for signature 'Vector,Vector'
split(x, f, drop=FALSE, ...)

## S4 method for signature 'list,Vector'
split(x, f, drop=FALSE, ...)

splitAsList(x, f, drop=FALSE, ...)

relistToClass(x)
```

Arguments

- `x, f`  
  2 vector-like objects of the same length. `f` will typically be a factor, but not necessarily.
- `drop`  
  Logical indicating if levels that do not occur should be dropped (if `f` is a factor).
- `...`  
  Extra arguments passed to any of the first 3 `split()` methods will be passed to `splitAsList()` (see Details below).
  Extra arguments passed to the last `split()` method will be passed to `base::split()` (see Details below).
  Extra arguments passed to `splitAsList()` will be passed to the specific method selected by method dispatch.

Details

The first 3 `split()` methods just delegate to `splitAsList()`.

The last `split()` method just does:

```r
split(x, as.vector(f), drop=drop, ...)
```

`splitAsList()` is an S4 generic function. It is the workhorse behind the first 3 `split()` methods above. It behaves like `base::split()` except that it returns a `List` derivative instead of an ordinary list. The exact class of this `List` derivative depends only on the class of `x` and can be obtained independently with `relistToClass(x)`.

Note that `relistToClass(x)` is the opposite of `elementType(y)` in the sense that the former returns the class of the result of relisting (or splitting) `x` while the latter returns the class of the result of unlisting (or unsplitting) `y`. More formally, if `x` is an object that is relistable and `y` a list-like object:

```r
relistToClass(x) is class(relist(x, some_skeleton))
elementType(y) is class(unlist(y))
```
Therefore, for any object \( x \) for which \( \text{relistToClass}(x) \) is defined and returns a valid class, \( \text{elementType}(\text{new}(\text{relistToClass}(x))) \) should return \( \text{class}(x) \).

**Value**

\( \text{splitAsList()} \) and the first 3 \( \text{split()} \) methods behave like \texttt{base::split()} except that they return a \texttt{List} derivative (of class \( \text{relistToClass}(x) \)) instead of an ordinary list. Like with \texttt{base::split()}, all the list elements in this object have the same class as \( x \).

**See Also**

- The \texttt{split} function in the \texttt{base} package.
- The \texttt{relist} methods and \texttt{extractList} generic function defined in the \texttt{IRanges} package.
- \texttt{Vector} and \texttt{List} objects.
- \texttt{Rle} and \texttt{DataFrame} objects.

**Examples**

```r
## On an Rle object:
x <- \texttt{Rle}(101:105, 6:2)
\texttt{split(x, c("B", "B", "A", "B", "A"))}

## On a DataFrame object:
groups <- c("group1", "group2")
DF <- \texttt{DataFrame}(
  a=\texttt{letters}[1:10],
  i=101:110,
  group=\texttt{rep}(factor(groups, levels=groups), c(3, 7))
)
\texttt{split(DF, DF$group)}

## Use \texttt{splitAsList()} if you need to split an ordinary vector into a
## List object:
\texttt{split(letters, 1:2)} # ordinary list
\texttt{splitAsList(letters, 1:2)} # List object
```

**Description**

The \texttt{S4Vectors} package defines \texttt{stack} methods for \texttt{List} and \texttt{matrix} objects.

It also introduces \texttt{mstack()}, a variant of \texttt{stack} where the list is taken as the list of arguments in ....
Usage

## S4 method for signature 'List'
stack(x, index.var="name", value.var="value", name.var=NULL)

## S4 method for signature 'matrix'
stack(x, row.var=names(dimnames(x))[1L],
     col.var=names(dimnames(x))[2L],
     value.var="value")
mstack(..., .index.var="name")

Arguments

x                      A List derivative (for the stack method for List objects), or a matrix (for the stack method for matrix objects).
index.var, .index.var  A single string specifying the column name for the index (source name) column.
value.var               A single string specifying the column name for the values.
name.var                TODO
row.var, col.var        TODO
...                      The objects to stack. Each of them should be a Vector or vector (mixing the two will not work).

Details

As with `stack` on a list, stack on a List derivative constructs a DataFrame with two columns: one for the unlisted values, the other indicating the name of the element from which each value was obtained. index.var specifies the column name for the index (source name) column and value.var specifies the column name for the values.

[TODO: Document `stack()` method for matrix objects.]

See Also

• `stack` in the *utils* package.
• List and DataFrame objects.

Examples

```r
library(IRanges)
starts <- IntegerList(c(1, 5), c(2, 8))
ends <- IntegerList(c(3, 8), c(5, 9))
rgl <- IRangesList(start=starts, end=ends)
rangeDataFrame <- stack(rgl, "space", "ranges")
```
Subsetting utilities

Description

Low-level utility functions and classes defined in the S4Vectors package to support subsetting of vector-like objects. They are not intended to be used directly.

TransposedDataFrame-class

TransposedDataFrame objects

Description

The TransposedDataFrame class is a container for representing a transposed DataFrame object, that is, a rectangular data container where the rows are the variables and the columns the observations.

A typical situation for using a TransposedDataFrame object is when one needs to store a DataFrame object in the assay() component of a SummarizedExperiment object but the rows in the DataFrame object should correspond to the samples and the columns to the features. In this case the DataFrame object must first be transposed so that the variables in it run "horizontally" instead of "vertically". See the Examples section at the bottom of this man page for an example.

Details

TransposedDataFrame objects are constructed by calling t() on a DataFrame object.

Like for a DataFrame object, or, more generally, for a data-frame-like object, the length of a TransposedDataFrame object is its number of variables. However, unlike for a data-frame-like object, its length is also its number of rows, not its number of columns. For this reason, a TransposedDataFrame object is NOT considered to be a data-frame-like object.

Author(s)

Hervé Pagès

See Also

- DataFrame objects.
- SummarizedExperiment objects in the SummarizedExperiment package.
## A DataFrame object with 3 variables:

```r
df <- DataFrame(aa=101:126, bb=letters, cc=Rle(c(TRUE, FALSE), 13),
    row.names=LETTERS)
dim(df)
length(df)

tdf <- t(df)
tdf
dim(tdf)
length(tdf)

tdf$aa

t(tdf) # back to 'df'
stopifnot(identical(df, t(tdf)))

tdf$aa <- 0.05 * tdf$aa
```

```r
x1 <- DataFrame(A=1:5, B=letters[1:5], C=11:15)
y1 <- DataFrame(B=c(FALSE, NA, TRUE), C=c(FALSE, NA, TRUE), A=101:103)
cbind(t(x1), t(y1))
stopifnot(identical(t(rbind(x1, y1)), cbind(t(x1), t(y1))))
```

## A TransposedDataFrame object can be used in the assay() component of a
## SummarizedExperiment object if the transposed layout is needed i.e. if
## the rows and columns of the original DataFrame object need to be treated
## as the samples and features (in this order) of the SummarizedExperiment
## object:

```r
library(SummarizedExperiment)
se1 <- SummarizedExperiment(df)
se1
assay(se1) # the 3 variables run "vertically"

se2 <- SummarizedExperiment(tdf)
se2
assay(se2) # the 3 variables run "horizontally"
```

---

**Vector-class**

**Vector objects**

### Description

The Vector virtual class serves as the heart of the S4Vectors package and has over 90 subclasses. It serves a similar role as vector in base R.

The Vector class supports the storage of *global* and *element-wise* metadata:

1. The *global* metadata annotates the object as a whole: this metadata is accessed via the metadata accessor and is represented as an ordinary list;
2. The element-wise metadata annotates individual elements of the object: this metadata is accessed via the mcols accessor (mcols stands for metadata columns) and is represented as a DataFrame object with a row for each element and a column for each metadata variable. Note that the element-wise metadata can also be NULL.

To be functional, a class that inherits from Vector must define at least a length and a "[" method.

Accessors

In the following code snippets, x is a Vector object.

length(x): Get the number of elements in x.
lengths(x, use.names=TRUE): Get the length of each of the elements.
   Note: The lengths method for Vector objects is currently defined as an alias for elementNROWS (with addition of the use.names argument), so is equivalent to sapply(x, NROW), not to sapply(x, length).

NROW(x): Equivalent to either nrow(x) or length(x), depending on whether x has dimensions (i.e. dim(x) is not NULL) or not (i.e. dim(x) is NULL).

names(x), names(x) <- value: Get or set the names of the elements in the Vector.

rename(x, value, ...): Replace the names of x according to a mapping defined by a named character vector, formed by concatenating value with any arguments in .... The names of the character vector indicate the source names, and the corresponding values the destination names. This also works on a plain old vector.

unname(x): removes the names from x, if any.

nlevels(x): Returns the number of factor levels.

mcols(x, use.names=TRUE), mcols(x) <- value: Get or set the metadata columns. If use.names=TRUE and the metadata columns are not NULL, then the names of x are propagated as the row names of the returned DataFrame object. When setting the metadata columns, the supplied value must be NULL or a DataFrame object holding element-wise metadata.

elementMetadata(x, use.names=FALSE), elementMetadata(x) <- value, values(x, use.names=FALSE), values(x) <- value: Alternatives to mcols functions. Their use is discouraged.

Coercion

as(from, "data.frame"), as.data.frame(from): Coerces from a Vector, to a data.frame by first coercing the Vector to a vector via as.vector. Note that many Vector derivatives do not support as.vector, so this coercion is possible only for certain types.

as.env(x): Constructs an environment object containing the elements of mcols(x).

Subsetting

In the code snippets below, x is a Vector object.

x[i]: When supported, return a new Vector object of the same class as x made of the elements selected by i. i can be missing; an NA-free logical, numeric, or character vector or factor (as ordinary vector or Rle object); or a IntegerRanges object.
**x[i, j]**: Like the above, but allow the user to conveniently subset the metadata columns thru j.

**NOTE TO DEVELOPERS:** A Vector subclass with a true 2-D semantic (e.g. `SummarizedExperiment`) needs to overwrite the "[" method for Vector objects. This means that code intended to operate on an arbitrary Vector derivative x should not use this feature as there is no guarantee that x supports it. For this reason this feature should preferably be used interactively only.

**x[i] <- value**: Replacement version of **x[i]**.

### Convenience wrappers for common subsetting operations

In the code snippets below, x is a Vector object.

- **subset(x, subset, select, drop=FALSE, ...)**: Return a new Vector object made of the subset using logical vector subset, where missing values are taken as FALSE. TODO: Document select, drop, and ... .
- **window(x, start=NA, end=NA, width=NA)**: Extract the subsequence from x that corresponds to the window defined by start, end, and width. At most 2 of start, end, and width can be set to a non-NA value, which must be a non-negative integer. More precisely:
  - If width is set to NA, then start or end or both can be set to NA. In this case start=NA is equivalent to start=1 and end=NA is equivalent to end=length(x).
  - If width is set to a non-negative integer value, then one of start or end must be set to a non-negative integer value and the other one to NA.
- **head(x, n=6L)**: If n is non-negative, returns the first n elements of the Vector object. If n is negative, returns all but the last abs(n) elements of the Vector object.
- **tail(x, n=6L)**: If n is non-negative, returns the last n elements of the Vector object. If n is negative, returns all but the first abs(n) elements of the Vector object.
- **rev(x)**: Return a new Vector object made of the original elements in the reverse order.
- **rep(x, times, length.out, each)** and **rep.int(x, times)**: Repeats the values in x through one of the following conventions:
  - **times**: Vector giving the number of times to repeat each element if of length length(x), or to repeat the whole vector if of length 1.
  - **length.out**: Non-negative integer. The desired length of the output vector.
  - **each**: Non-negative integer. Each element of x is repeated each times.

### Concatenation

In the code snippets below, x is a Vector object.

- **c(x, ..., ignore.mcols=FALSE)**: Concatenate x and the Vector objects in ... together. Any object in ... should belong to the same class as x or to one of its subclasses. If not, then an attempt will be made to coerce it with as(object, class(x), strict=FALSE). NULLs are accepted and ignored. The result of the concatenation is an object of the same class as x.

Handling of the metadata columns:

- If only one of the Vector objects has metadata columns, then the corresponding metadata columns are attached to the other Vector objects and set to NA.
• When multiple Vector objects have their own metadata columns, the user must ensure that each such DataFrame have identical layouts to each other (same columns defined), in order for the concatenation to be successful, otherwise an error will be thrown.

• The user can call \texttt{c(x, \ldots, ignore.mcols=FALSE)} in order to concatenate Vector objects with differing sets of metadata columns, which will result in the concatenated object having NO metadata columns.

IMPORTANT NOTE: Be aware that calling \texttt{c} with named arguments (e.g. \texttt{c(a=x, b=y)}) tends to break method dispatch so please make sure that \texttt{args} is an \texttt{unnamed} list when using \texttt{do.call(c, args)} to concatenate a list of objects together.

\texttt{append(x, values, after=length(x))}: Insert the Vector values onto \texttt{x} at the position given by \texttt{after}. \texttt{values} must have an \texttt{elementType} that extends that of \texttt{x}.

\texttt{expand.grid(...)}: Find cartesian product of every vector in \texttt{...} and return a data.frame, each column of which corresponds to an argument. See \texttt{expand.grid}.

Displaying

[FOR ADVANCED USERS OR DEVELOPERS]

Displaying of a Vector object is controlled by 2 internal helpers, \texttt{classNameForDisplay} and \texttt{showAsCell}. For most objects \texttt{classNameForDisplay(x)} just returns \texttt{class(x)}. However, for some objects it can return the name of a parent class that is more suitable for display because it’s simpler and as informative as the real class name. See \texttt{SimpleList} objects (defined in this package) and \texttt{CompressedList} objects (defined in the \texttt{IRanges} package) for examples of objects for which \texttt{classNameForDisplay} returns the name of a parent class.

\texttt{showAsCell(x)} produces a character vector \texttt{parallel} to \texttt{x} (i.e. with one string per vector element in \texttt{x}) that contains compact string representations of each elements in \texttt{x}.

Note that \texttt{classNameForDisplay} and \texttt{showAsCell} are generic functions so developers can implement methods to control how their own Vector extension gets displayed.

See Also

• \texttt{Rle}, \texttt{Hits}, \texttt{IRanges} and \texttt{XRaw} for example implementations.
• \texttt{Vector-comparison} for comparing, ordering, and tabulating vector-like objects.
• \texttt{Vector-setops} for set operations on vector-like objects.
• \texttt{Vector-merge} for merging vector-like objects.
• \texttt{Factor} for a direct Vector extension that serves a similar role as \texttt{factor} in base R.
• \texttt{List} for a direct Vector extension that serves a similar role as \texttt{list} in base R.
• \texttt{extractList} for grouping elements of a vector-like object into a list-like object.
• \texttt{DataFrame} which is the type of object returned by the \texttt{mcols} accessor.
• The \texttt{Annotated} class, which Vector extends.

Examples

\texttt{showClass("Vector")} # shows (some of) the known subclasses
Vector-comparison  

Compare, order, tabulate vector-like objects

Description

Generic functions and methods for comparing, ordering, and tabulating vector-like objects.

Usage

## Element-wise (aka "parallel") comparison of 2 Vector objects
## ----------------------------------------------------------

pcompare(x, y)

## S4 method for signature 'Vector,Vector'
e1 == e2
## S4 method for signature 'Vector,ANY'
e1 == e2
## S4 method for signature 'ANY,Vector'
e1 == e2

## S4 method for signature 'Vector,Vector'
e1 <= e2
## S4 method for signature 'Vector,ANY'
e1 <= e2
## S4 method for signature 'ANY,Vector'
e1 <= e2

## S4 method for signature 'Vector,Vector'
e1 != e2
## S4 method for signature 'Vector,ANY'
e1 != e2
## S4 method for signature 'ANY,Vector'
e1 != e2

## S4 method for signature 'Vector,Vector'
e1 >= e2
## S4 method for signature 'Vector,ANY'
e1 >= e2
## S4 method for signature 'ANY,Vector'
e1 >= e2

## S4 method for signature 'Vector,Vector'
e1 < e2
## S4 method for signature 'Vector,ANY'
e1 < e2
## S4 method for signature 'ANY,Vector'
\begin{verbatim}
e1 < e2
## S4 method for signature 'Vector,Vector'
e1 > e2
## S4 method for signature 'Vector,ANY'
e1 > e2
## S4 method for signature 'ANY,Vector'
e1 > e2

## sameAsPreviousROW()
## -------------------
sameAsPreviousROW(x)

## match()
## -------
## S4 method for signature 'Vector,Vector'
match(x, table, nomatch = NA_integer_,
       incomparables = NULL, ...)

## selfmatch()
## -----------
selfmatch(x, ...)

## S4 method for signature 'Vector'  
rank(x, na.last = TRUE, ties.method = c("average",  
  "first", "last", "random", "max", "min"), by)  

## xtfrm()  
## -------  
## S4 method for signature 'Vector'  
xfrm(x)  

## table()  
## -------  
## S4 method for signature 'Vector'  
table(...)  

**Arguments**  

*x, y, e1, e2, table*  
Vector-like objects.  

*nomatch*  
See ?base::match.  

*incomparables*  
The duplicated method for Vector objects does NOT support this argument.  
The unique method for Vector objects, which is implemented on top of duplicated,  
propagates this argument to its call to duplicated.  
See ?base::duplicated and ?base::unique for more information about this  
argument for these generics.  
The match method for Vector objects does support this argument, see ?base::match  
for details.  

*select*  
Only select="all" is supported at the moment. Note that you can use `match`  
if you want to do select="first". Otherwise you're welcome to request this  
on the Bioconductor mailing list.  

*ties.method*  
See ?base::rank.  

decreasing, na.last  
See ?base::sort.
A formula referencing the metadata columns by which to sort, e.g., \( \sim x + y \) sorts by column “x”, breaking ties with column “y”.

... A Vector object for table (the table method for Vector objects can only take one input object).

Otherwise, extra arguments supported by specific methods. In particular:

- The default selfmatch method, which is implemented on top of match, propagates the extra arguments to its call to match.
- The duplicated method for Vector objects, which is implemented on top of selfmatch, accepts extra argument fromLast and propagates the other extra arguments to its call to selfmatch. See \texttt{?base::duplicated} for more information about this argument.
- The unique method for Vector objects, which is implemented on top of duplicated, propagates the extra arguments to its call to duplicated.
- The default findMatches and countMatches methods, which are implemented on top of match and selfmatch, propagate the extra arguments to their calls to match and selfmatch.
- The sort method for Vector objects, which is implemented on top of order, only accepts extra argument na.last and propagates it to its call to order.

Details

Doing \texttt{pcompare(x, y)} on 2 vector-like objects \( x \) and \( y \) of length 1 must return an integer less than, equal to, or greater than zero if the single element in \( x \) is considered to be respectively less than, equal to, or greater than the single element in \( y \). If \( x \) or \( y \) have a length \(!= 1\), then they are typically expected to have the same length so \texttt{pcompare(x, y)} can operate element-wise, that is, in that case it returns an integer vector of the same length as \( x \) and \( y \) where the \( i \)-th element is the result of comparing \( x[i] \) and \( y[i] \). If \( x \) and \( y \) don’t have the same length and are not zero-length vectors, then the shortest is first recycled to the length of the longest. If one of them is a zero-length vector then \texttt{pcompare(x, y)} returns a zero-length integer vector.

\texttt{selfmatch(x, ...)} is equivalent to \texttt{match(x, x, ...)}. This is actually how the default \texttt{ANY} method is implemented. However note that the default \texttt{selfmatch(x, ...)} for Vector \( x \) will typically be more efficient than \texttt{match(x, x, ...)}, and can be made even more so if a specific \texttt{selfmatch} method is implemented for a given subclass.

\texttt{findMatches} is an enhanced version of \texttt{match} which, by default (i.e. if \texttt{select}="all"), returns all the matches in a Hits object.

\texttt{countMatches} returns an integer vector of the length of \( x \) containing the number of matches in table for each element in \( x \).

Value

For \texttt{pcompare}: see Details section above.

For \texttt{sameAsPreviousROW}: a logical vector of length equal to \( x \), indicating whether each entry of \( x \) is equal to the previous entry. The first entry is always \texttt{FALSE} for a non-zero-length \( x \).

For \texttt{match} and \texttt{selfmatch}: an integer vector of the same length as \( x \).

For \texttt{duplicated}, \texttt{unique}, and \texttt{%in%}: see \texttt{?BiocGenerics::duplicated}, \texttt{?BiocGenerics::unique}, and \texttt{?%in%}.
For findMatches: a Hits object by default (i.e. if select="all").

For countMatches: an integer vector of the length of x containing the number of matches in table for each element in x.

For sort: see ?BiocGenerics::sort.

For xtfrm: see ?base::xtfrm.

For table: a 1D array of integer values promoted to the "table" class. See ?BiocGeneric::table for more information.

Note

The following notes are for developers who want to implement comparing, ordering, and tabulating methods for their own Vector subclass.

Subclass comparison methods can be split into various categories. The first category must be implemented for each subclass, as these do not have sensible defaults for arbitrary Vector objects:

• The S4Vectors package provides no order method for Vector objects. So calling order on a Vector derivative for which no specific order method is defined will use base::order, which calls xtfrm, with in turn calls order, which calls xtfrm, and so on. This infinite recursion of S4 dispatch eventually results in an error about reaching the stack limit.

To avoid this behavior, a specialized order method needs to be implemented for specific Vector subclasses (e.g. for Hits and IntegerRanges objects).

• sameAsPreviousROW is default implemented on top of the == method, so will work out-of-the-box on Vector objects for which == works as expected. However, == is default implemented on top of pcompare, which itself has a default implementation that relies on sameAsPreviousROW!

This again leads to infinite recursion and an error about the stack limit.

To avoid this behavior, a specialized sameAsPreviousROW method must be implemented for specific Vector subclasses.

The second category contains methods that have default implementations provided for all Vector objects and their derivatives. These methods rely on the first category to provide sensible default behaviour without further work from the developer. However, it is often the case that greater efficiency can be achieved for a specific data structure by writing a subclass-specific version of these methods.

• The pcompare method for Vector objects is implemented on top of order and sameAsPreviousROW, and so will work out-of-the-box on Vector derivatives for which order and sameAsPreviousROW work as expected.

• The xtfrm method for Vector objects is also implemented on top of order and sameAsPreviousROW, and so will also work out-of-the-box on Vector derivatives for which order and sameAsPreviousROW work as expected.

• selfmatch is itself implemented on top of xtfrm (indirectly, via grouping) so it will work out-of-the-box on Vector objects for which xtfrm works as expected.

• The match method for Vector objects is implemented on top of selfmatch, so works out-of-the-box on Vector objects for which selfmatch works as expected.

(A careful reader may notice that xtfrm and order could be swapped between categories to achieve the same effect. Similarly, sameAsPreviousROW and pcompare could also be swapped. The exact
categorization of these methods is left to the discretion of the developer, though this is mostly academic if both choices are specialized.)

The third category also contains methods that have default implementations, but unlike the second category, these defaults are straightforward and generally do not require any specialization for efficiency purposes.

- The 6 traditional binary comparison operators are: \(==\), \(!=\), \(<\), \(\leq\), \(\geq\), and \(>\). The \texttt{S4Vectors} package provides the following methods for these operators:

```r
setMethod("==", c("Vector", "Vector"),
  function(e1, e2) { pcompare(e1, e2) == 0L })
setMethod("<=", c("Vector", "Vector"),
  function(e1, e2) { pcompare(e1, e2) <= 0L })
setMethod("!=" , c("Vector", "Vector"),
  function(e1, e2) { !(e1 == e2) })
setMethod(">=", c("Vector", "Vector"),
  function(e1, e2) { e2 <= e1 })
setMethod("<", c("Vector", "Vector"),
  function(e1, e2) { !e2 <= e1 })
setMethod(">", c("Vector", "Vector"),
  function(e1, e2) { !e1 <= e2 })
```

With these definitions, the 6 binary operators work out-of-the-box on \texttt{Vector} objects for which \texttt{pcompare} works the expected way. If \texttt{pcompare} is not implemented, then it's enough to implement \(==\) and \(\leq\) methods to have the 4 remaining operators \(!=\), \(\geq\), \(<\), and \(>\) work out-of-the-box.

- The duplicated, unique, and \%in\% methods for \texttt{Vector} objects are implemented on top of \texttt{selfmatch}, \texttt{duplicated}, and \texttt{match}, respectively, so they work out-of-the-box on \texttt{Vector} objects for which \texttt{selfmatch}, \texttt{duplicated}, and \texttt{match} work the expected way.

- Also the default \texttt{findMatches} and \texttt{countMatches} methods are implemented on top of \texttt{match} and \texttt{selfmatch} so they work out-of-the-box on \texttt{Vector} objects for which those things work the expected way.

- The \texttt{sort} method for \texttt{Vector} objects is implemented on top of \texttt{order}, so it works out-of-the-box on \texttt{Vector} objects for which \texttt{order} works the expected way.

- The \texttt{table} method for \texttt{Vector} objects is implemented on top of \texttt{selfmatch}, \texttt{order}, and \texttt{as.character}, so it works out-of-the-box on a \texttt{Vector} object for which those things work the expected way.

Examples

```r
## A. SIMPLE EXAMPLES

y <- c(16L, -3L, -2L, 15L, 15L, 0L, 8L, 15L, -2L)
selfmatch(y)

x <- c(unique(y), 999L)
findMatches(x, y)
countMatches(x, y)
```

```
## See ?"IntegerRanges-comparison" for more examples (on IntegerRanges objects). You might need to load the IRanges package first.
```

## B. FOR DEVELOPERS: HOW TO IMPLEMENT THE BINARY COMPARISON OPERATORS

```
## FOR YOUR Vector SUBCLASS

## The answer is: don't implement them. Just implement pcompare() and the binary comparison operators will work out-of-the-box. Here is an example:

## (1) Implement a simple Vector subclass.

setClass("Raw", contains="Vector", representation(data="raw"))

setMethod("length", "Raw", function(x) length(x@data))

setMethod("[", "Raw",

    function(x, i, j, ..., drop) { x@data <- x@data[i]; x }
)

x <- new("Raw", data=charToRaw("AB.x0a-BAA+C"))
```
stopifnot(identical(length(x), 12L))
stopifnot(identical(x[7:3], new("Raw", data=charToRaw("-a0x."))))

## (2) Implement a "pcompare" method for Raw objects.

setMethod("pcompare", c("Raw", "Raw"),
  function(x, y) {as.integer(x@data) - as.integer(y@data)}
)
stopifnot(identical(which(x == x[1]), c(1L, 9L, 10L)))
stopifnot(identical(x[x < x[5]], new("Raw", data=charToRaw(".-+"))))

Vector-merge

Merge vector-like objects

Description

A merge method for vector-like objects.

Usage

## S4 method for signature 'Vector,Vector'
merge(x, y, ..., all=FALSE, all.x=NA, all.y=NA, sort=TRUE)

Arguments

x, y, ... Vector-like objects, typically all of the same class and typically not list-like objects (even though some list-like objects like IntegerRanges and DNAStringSet are supported). Duplicated elements in each object are removed with a warning.

all TRUE or FALSE. Whether the vector elements in the result should be the union (when all=TRUE) or intersection (when all=FALSE) of the vector elements in x, y, ....

all.x, all.y To be used only when merging 2 objects (binary merge). Both all.x and all.y must be single logicals. If any of them is NA, then it’s set to the value of all. Setting both of them to TRUE or both of them to FALSE is equivalent to setting all to TRUE or to FALSE, respectively (see above).

If all.x is TRUE and all.y is FALSE then the vector elements in the result will be the unique elements in x. If all.x is FALSE and all.y is TRUE then the vector elements in the result will be the unique elements in y.

sort Whether to sort the merged result.

Details

This merge method acts much like merge.data.frame, except for 3 important differences:

1. The matching is based on the vector values, not arbitrary columns in a table.
2. Self merging is a no-op if sort=FALSE (or object already sorted) and if the object has no duplicates.
3. This `merge` method accepts an arbitrary number of vector-like objects (n-ary merge).

If some of the objects to merge are list-like objects not supported by the method described here, then the merging is simply done by calling `base::merge()` on the objects. This might succeed or not...

**Value**

A vector-like object of the same class as the input objects (if they all have the same class) containing the merged vector values and metadata columns.

**See Also**

- The `Vector` class.
- `Vector-comparison` for comparing and ordering vector-like objects.
- `Vector-setops` for set operations on vector-like objects.

**Examples**

```r
library(GenomicRanges)
x <- GRanges(c("chr1:1-1000", "chr2:2000-3000"),
            score=c(0.45, 0.1), a1=c(5L, 7L), a2=c(6, 8))
y <- GRanges(c("chr2:150-151", "chr1:1-10", "chr2:2000-3000"),
            score=c(0.7, 0.82, 0.1), b1=c(0L, 5L, 1L), b2=c(1, -2, 1))
merge(x, y)
merge(x, y, all=TRUE)
merge(x, y, all.x=TRUE)
merge(x, y, all.y=TRUE)

## Shared metadata columns must agree:
mcols(x)$score[2] <- 0.11
#merge(x, y) # error!

## NAs agree with anything:
mcols(x)$score[2] <- NA
merge(x, y)
```

---

**Vector-setops**

*Set operations on vector-like objects*

**Description**

Perform set operations on `Vector` objects.
Usage

```r
## S4 method for signature 'Vector,Vector'
union(x, y)

## S4 method for signature 'Vector,Vector'
intersect(x, y)

## S4 method for signature 'Vector,Vector'
setdiff(x, y)

## S4 method for signature 'Vector,Vector'
setequal(x, y)
```

Arguments

- `x, y` Vector-like objects.

Details

The `union`, `intersect`, and `setdiff` methods for `Vector` objects return a `Vector` object containing respectively the union, intersection, and (asymmetric!) difference of the 2 sets of vector elements in `x` and `y`. The `setequal` method for `Vector` objects checks for set equality between `x` and `y`.

They're defined as follow:

```r
setMethod("union", c("Vector", "Vector"),
  function(x, y) unique(c(x, y))
)
setMethod("intersect", c("Vector", "Vector"),
  function(x, y) unique(x[x %in% y])
)
setMethod("setdiff", c("Vector", "Vector"),
  function(x, y) unique(x[!(x %in% y)])
)
setMethod("setequal", c("Vector", "Vector"),
  function(x, y) all(x %in% y) && all(y %in% x)
)
```

so they work out-of-the-box on `Vector` objects for which `c`, `unique`, and `%in%` are defined.

Value

- `union` returns a `Vector` object obtained by appending to `x` the elements in `y` that are not already in `x`.
- `intersect` returns a `Vector` object obtained by keeping only the elements in `x` that are also in `y`.
- `setdiff` returns a `Vector` object obtained by dropping from `x` the elements that are in `y`.
- `setequal` returns `TRUE` if `x` and `y` contain the same sets of vector elements and `FALSE` otherwise.
zip-methods

union, intersect, and setdiff propagate the names and metadata columns of their first argument (x).

```

zip-methods

Convert between parallel vectors and lists

Description

The zipup and zipdown functions convert between two parallel vectors and a list of doublets (elements of length 2). The metaphor, borrowed from Python’s zip, is that of a zipper. The zipup function interleaves the elements of the parallel vectors into a list of doublets. The inverse operation is zipdown, which returns a `Pairs` object.

Usage

```r
zipup(x, y, ...)  
zipdown(x, ...)
```

Arguments

- `x, y` For zipup, any vector-like object. For zipdown, a doublet list.
- `...` Arguments passed to methods.

Value

For zipup, a list-like object, where every element is of length 2. For zipdown, a `Pairs` object.

See Also

- `Pairs` objects.
Examples

```r
z <- zipup(1:10, Rle(1L, 10))
pairs <- zipdown(z)
```
